Modern Physics and the Atom.

IN another part of this issue we publish as a special supplement a translation of Prof. N. Bohr's lecture on atomic structure, which was delivered at Stockholm last December on the occasion of receiving the Nobel prize for physics. It seems a fitting occasion to survey the general lines of the recent development of physical theories as to the nature of the atom. The views put forward in Prof. Bohr's address may fairly be regarded as the furthest stage yet reached.

The leading feature of the physics of the twentieth century has been the development of our present concrete picture of the individual atom. In this respect modern physics stands rightly in sharp contrast with previous work—properties of matter in bulk, thermodynamic, electrodynamic, and optical theory. These theories formed the main part of the studies and contributions of physicists before 1900, and advanced with particular rapidity in the latter half of the last century. In all this work, though the atomic nature of matter had already come to general recognition in virtue perhaps of chemical rather than physical evidence, atoms, if recognised at all, play only a secondary part. The reason is that though theories of matter (*e.g.* gases) may be built up on an atomic basis, applications of these theories are always *statistical*; in making them an averaging process is used, and the particular features of an atomic model largely disappear. For example, almost any atomic model will reproduce the main properties of a gas. It is only in the finer points such as the exact variation of viscosity with temperature that the particular form of atomic model becomes relevant, and even here the variation deduced is very insensitive to the model chosen. Crude and vague ideas of the atom—little more than the mere recognition of its existence—were all that were necessary to physics in this phase.

The same is true in a somewhat less striking way of the electronic conception of electricity. This idea became current in a vague form and was shown to be a suitable foundation for the known phenomena of electricity; it was not till some years later that the fundamental experiments on the conduction of electricity through gases first led to a practical demonstration of the existence and main properties of the electron. Just as with atoms, a break-away from statistical deductions was necessary before the electron could be assigned a definite form. The demonstration of its existence and properties, though it belongs historically (1897) to the nineteenth century, is in fact the starting point of what we have called twentieth-century physics.

This concentration on the statistical side was of course inevitable, for the phenomena to which current theories could be applied were mainly concerned, as we have said, with the properties of matter or electricity in bulk. There were, of course, striking and significant exceptions which were already well known for many years before 1900—for example, optical spectra. These had long been recognised as essentially characteristic of particular atoms or molecules, obscured little if at all by any process of averaging. But optical spectra are too complicated and their conditions of excitation too obscure to have formed then a possible basis on which to build theories of atomic structure with any real chance of success. It was necessary to wait first for direct experimental evidence of the more fundamental properties of individual atoms which are unaffected by the widest possible range of external circumstances. It is clear that it is such properties that any atomic model must first set out to reproduce.

The discovery of the nature and properties of X-rays might have provided a new and more hopeful starting point. Here we have evidence of fundamental properties which remain constant and characteristic in all known circumstances. But even this evidence—even, for example, an empirical formulation of Moseley's law—would scarcely have been simple and direct enough for a starting point, and in fact was not available until after the first essential ideas had been otherwise won. The evidence necessary for the start had clearly to refer directly to individual atoms and be such as to lay down with absolute convincingness the main features of atomic structure. It was provided first by the study of radioactivity, and it is difficult to see, as we have tried to show, how any other evidence could have been sufficiently powerful for the purpose. The radioactive evidence soon made it clear that here physicists were concerned with processes connected with the most intimate structure of the individual atom, which outside conditions (physical or chemical) were powerless to affect; and concerned, too, with energy transformations in a single atom so large that the resulting effects could actually be detected. This made it clear that the atom must have an innermost structure, a place apart, the seat of gigantic forces. Ideas of the atom thus began to tend generally in the right direction, and crystallised into the nuclear atom when the nature of the α-particle had been established and the phenomena of its scattering worked out.

It was at this point (1911) that Prof. Bohr's contributions began, and it is convenient to specify the situation in somewhat more detail. It was known that the atom must almost certainly consist of a heavy nucleus, of extremely small size, with a positive electric charge; this nucleus must probably behave, so far as the rest of the world or even the rest of the atom was concerned, as a massive point charge. The nuclear charge must be neutralised in the natural atom by a system of satellite electrons in number equal to the number of units in the nuclear charge. Their arrangement was, however, quite unknown, except that they must with the nucleus compose a structure on the scale of the atom of gas theory—a scale which is exceedingly large and open compared to the dimensions of the nucleus and the electrons themselves. The exact number of satellite electrons or units of nuclear charge was also uncertain, but, by the results of X-ray and α-particle scattering, must be about half the atomic weight. It was almost certain that it was two for helium and one for hydrogen. If these views were to be accepted the hydrogen atom must be very simple—a single heavy nucleus with a unit positive charge, and somewhere near it a single electron; it must also yield the known series spectrum of hydrogen. This was the problem presented to Prof. Bohr. He maintained from the first, and justly as is now admitted by all, that there was no possibility of a solution within the domain of classical electrodynamics, and that the ideas of the quantum theory must be invoked. How these ideas lead inevitably to the accepted hydrogen atom of to-day is set forth at length in the first of his three essays, "The Theory of Spectra and Atomic Constitution," referred to in NATURE of April 21, p. 523, and, more shortly, in the present supplement.

The next essential step was the final assignment of *atomic number*, which connected up once and for all the ordinal number of any atom in the periodic table of the elements, its nuclear charge, the number of its satellite electrons, and its characteristic X-ray spectrum. This assignment, which was, of course, the result of a systematic survey of X-ray spectra, was to some extent directly inspired by the successful theory of the hydrogen atom, and without that theory the full

significance of atomic number would have been missed. At this stage (1915) a general grasp had been obtained of the sequence of the elements and of the essential difference between one atom and the next, in full agreement with evidence of an entirely different type—the displacement laws of α- and β-particle radioactive changes.

In the further elucidation of the organisation of the satellite electrons and the interpretation of the periodic table of the elements, Prof. Bohr has played the leading part. The results obtained are described by Prof. Bohr at length in our supplement. It is sufficient to say here that, thanks to this work, we are now confident that the satellite electrons are arranged in groups. We know the number of electrons in each group. They move about the nucleus in orbits, some of the characteristics of which we already know, and these characteristics are the same for all the electrons of a group. We know, further, the order in which the various groups appear in the system of the elements, and even to a limited extent why the actual order must be observed. This information is summarised in the supplement (Fig. 9). The details of the picture—important details—have yet to be filled in, but we can no longer doubt that we are advancing on the right lines.

In conclusion, one may glance for a moment at the profound reaction of these views of atomic structure on physical research. In return for their spectroscopic basis in the Balmer series, they have revolutionised spectroscopy, which is now—X-ray and optical alike—one of the main avenues of advance in physics. They have created a whole new and fruitful branch of study, the excitation of atoms by electronic impacts. They provide a concrete picture of the atom which can form, and is forming every day, a trustworthy basis for the study of all branches of atomic phenomena. Finally, one must expect that the facts of chemistry will not much longer stand apart. Though much formal progress has already been made in the theory of valency, the detailed electronic theory of the structure of molecules has yet to be begun; it will inevitably present grave difficulties. But these views of atomic structure have, for example, already presented us (unasked) with a carbon atom with tetrahedral symmetry; they lead us confidently to expect that the first advances in the detailed theory will not be long delayed.

The Conquest of Malaria.

Memoirs: With a Full Account of the Great Malaria Problem and its Solution. By Ronald Ross. Pp. xi + 547 + 11 plates. (London: John Murray, 1923.) 24*s*. net.

IN Sir Ronald Ross's "Memoirs" information is to be found which will interest the conventional "wide circle of readers," in that the subjects treated must appeal to the Imperialist, the political economist, the sanitarian of the tropics, and the cosmopolitan science research worker; nor will those who respond to the "call of the East" fail to find interest in details of scenery and travels in India and Burma. Among the items illustrating the importance of research in aiding the well-being of communities and nations are discussed the conditions under which the discovery of the agency of malaria conveyance was made, as a result of the laborious experimental efforts of the author. In the section dealing with this subject will be found a tale devoid of technicalities of relentless search for a scientific truth, with its recurring disappointments, baffled schemes, renewed hopes, and ultimate victory, which, in entrancing interest, may compete with Sherlock Holmes's efforts at his best.

For centuries, the problem of malaria afforded a favourite subject in medical writings for opinions and disputations. By 1880 Laveran had found the *plasmodium malariæ* in the blood of human beings; but the vital matter, in respect to prevention, as to how the protozoon gained entrance to man remained a mystery. In 1894 Manson excogitated an hypothesis as to malaria agency, which was published in detail in the *Lancet* (vol. 1., p. 1309). Ross was in England in that year. Between the younger man, eager to remedy the distressing conditions arising from this cause in India, and the older, glad to find an enthusiast in malaria prevention, there arose a mutual professional interest and interchange of views, which continued during Ross's labour in that country. It has since been insisted that Ross was a mere marionette under the control of Manson; indeed, that he was "selected"[1] by the latter for this particular work, and that Manson was the "discoverer of malaria."

Where admiration for Manson can justly be given in this matter is in contemplating his reasons for framing the hypothesis of 1894, namely, that it might prove an incentive to research on malaria which, as he asserted (*Journal of State Medicine*, September 1900), "is far and away the most important of the many problems of tropical empire—that empire upon which so much of our present and of our prospective national prosperity depends." No claim to originality was made by him, and with the one exception (added in 1898 to the original conjecture of 1894) that the flagella

[1] This is a particularly inapt contention, seeing that before Ross "selected" himself for this limitless task (p. 131, "Memoirs"), Manson had issued with his hypothesis of 1894 an invitation to medical men in India generally (*British Medical Journal*, vol. i. p. 1309) to undertake research on the lines suggested, and, after Ross had furnished him with results, repeated this invitation in 1896 (*B.M.J.* March 28). In 1898, when Ross had arrived at an important stage of his discovery (*B.M.J.* p. 1576, 1898), Manson decided "again to call the attention of workers on malaria to this promising field for investigation." Further, Ross, both officially and privately, in India strove to induce others independently to undertake the task. Meanwhile Manson did not utilise material available in England (pp. 131, 147 "Memoirs").

of the plasmodium were "flagellated-spores" (which was an error), no originality is recognizable. By dovetailing various views of acknowledged authorities with the analogy of filariasis, as previously suggested by Laveran, he attempted to meet the then current opinion of transmission of malaria to man through the medium of air or water.

The "Memoirs" show that up to 1896 Ross had laboured to prove the hypothesis of Manson, and that mosquitoes, fleas, bugs, horse-flies, and cockroaches had been duly examined, while direct experiments upon human beings had been made as to conveyance by water, with the result that he informed Manson that "the belief is growing upon me that the disease is communicated by the bite of the mosquito" (pp. 176, 190, 193). To this Manson replied, "It may be the mosquito conveys the parasite by biting, but I do not think so—at all events, I do not think so directly." Ross now informed Manson that he was "dying to go away to some regular hotbed of malaria"—the object obviously being to secure possible factors in intense occurrence. He obtained short leave from military duty, and proceeded to a spot popularly held to be the haunt of a deadly form of malaria—Sigur Ghat in the Nilgiris Hills. This resolve was the turning-point of his investigation. A detail concerning his return to Bangalore, where he was stationed, does not appear in his "Memoirs." A friend perceived a mounted man approaching him gesticulating excitedly. This proved to be Ross, who shouted "I've got it—I've got it!" Naturally, a fortune by a sweepstake or the like was "sensed," but a demand for enlightenment elicited the banal reply, "I've got the fever." He had been able to concentrate attention upon air, water, and the mosquito as factors, with the crowning joy of suffering from fever; he was able to adopt a "mathematical line of reasoning," which pointed to the chances of the malarial germ being conveyed by the mosquito direct to man rather than in a form diluted by air or water. Thereafter, he could say with Newton that he did not deal with hypotheses but with facts. On August 20, 1897, Ross identified the first stage of development of the plasmodium in the mosquito. It would deprive the reader of interesting details were the further history of his efforts traced. Suffice it to say that by July 9, 1898, Ross *had not proved but had disproved Manson's hypothesis of 1894*.

Ross has roundly declared time after time, and in various forms, that it was Manson's "great induction which did it—nothing else," and that he had received advice from Manson. These affirmations have been misconstrued. Lister, after entering judicially into the attempted piracy of Ross's discovery by certain Italian savants, gave his opinion thus: "The discovery of the development of the parasite in the mosquito was due solely and simply to Major Ross, who had shown absolute candour, perfect openness of mind, and a readiness to recognise the work of others." Throughout the "Memoirs" these attributes are unconsciously displayed by the author.[2] The advice as to technique given by Manson was based upon special knowledge of filariasis—it was found inapplicable by Ross to his requirements; it was, nevertheless, courteously acknowledged. The "great induction" referred to the function of the flagella, and, when deprived of Manson's erroneous suggestion as to these being spores, did not differ materially from the views expressed previously by Laveran and Mannaberg. Ross, however, justly held that, by insisting that the flagella had some undiscovered yet important biological function, Manson had provided an *incentive* to research, which he handsomely acknowledged.

Manson had the gratification of finding that he had been the factor in inducing one man, among hundreds of potential workers to whom he had made an appeal broadcast, to undertake research on what he believed to be (*British Medical Journal*, 1898, p. 1576) "the logical outcome of well-ascertained facts, . . . and the most promising guide to fresh facts." That one man was Ross, whose inner consciousness, as early as 1890-93, had been stirred to discover means for averting the misery incident to malaria in the populations of India. In his poetic record, under the title "Indian Fevers," he had written, "O God reveal thro' all this thing obscure, the unseen, small, but million-murdering cause" ("Philosophies," p. 21); and, on the day when he realized that his invocation had been answered, wrote, "This day relenting, God hath placed within my hand a wondrous thing; and, God be praised, I know this little thing a myriad men will save."

Ross had definitely undertaken his research—not in the quest of abstract science—but in the interests of preventive medicine. His next hope therefore was to be allowed to apply methods based on his discovery. The Government of India (in which country one million deaths occur yearly from malaria), however, not only failed to issue so much as the usual stereotyped "thanks of Government," but also refused to promise him facilities. Rather than leave matters thus, he retired from the Indian Medical Service; with a pension one-fourth the value he might have secured

[2] At forty years of age, he had still to learn that the compendium to the tenth Commandment—"nor anything that is his"—was liable to be forgotten by pseudo-men of science, and that, with Governments, the axiom "Politics first" and "deil tak' the hinmost" allows little room for financing the interests of so trivial a fad as disease prevention. Difficulties encountered are factors in evolution—sometimes beneficent; in the case of the author, for many years since he arrived at that age of discretion, in public speeches and in literature, he has proved a powerful advocate of aid to research workers.

by continued service. But this personal sacrifice (added to the considerable private expenditure during his investigation) enabled him to complete his work, by demonstrating the applicability of its benefits in West Africa and Ismalia. The King-Emperor has conferred honours (not, however, upon the recommendation of the Government of India) upon the man who had made, as Manson said, the discovery of the century (p. 317).

Following the adoption of anti-malaria methods based on knowledge gained by Ross, invaliding and sickness in the British garrisons in the tropics have been reduced to an extent which must represent many thousand pounds—irrespective of human suffering—saved; great mercantile firms have extended trade to areas they formerly shunned from dread of the malaria fiend, and these share the benefits of commerce consequent upon the opening of the Panama Canal, the construction of which had proved impossible in the hands of the French—owing to the ghastly mortality of employees—in the absence of Ross's methods; during the great War, according to the Official History (vol. 2, p. 238), "the loss of the strength to the armies from the effects of malaria was great, and *but for the preventive methods adopted it might have been incalculably greater*" (italics not in the original). What has the nation, the Parliament of which voted 30,000*l.* to Jenner in token of gratitude, done for this practical philanthropist?

In "Memoirs" covering many years and many localities, the author has left little room for criticism as to accuracy. At p. 223, the date of his first gleam of success is erroneously stated in the text; fortunately, the next page is faced by a facsimile which correctly shows the date to have been August 20, 1897; at p. 327, in referring to Haffkine's good work, it is evident the date 1916 should read 1896; at p. 198, in reference to the use of "bird's malaria," the context would show that the intention is to refer to 1896 and not 1906. The Madras Presidency can claim freedom from the conception that (p. 200) "though plague had broken out for some years in China, almost no precautions had been taken to exclude it from India." It is inaccurate to describe Mr. E. H. Hankin, the able bacteriologist, as "the discoverer of the mode of purifying wells by permanganate of potassium." He did not initiate the method; to him is the credit of showing that the cholera vibrio is killed by the chemical, and is not starved out of existence by its action on organic matter. The Hindu title of "Maharaja" used in connexion with the independent potentate mentioned at p. 101 will doubtless be corrected in future editions of the work.

W. G. King.

Variable Stars.

Specola Astronomica Vaticana V. Herausgegeben von Johann Georg Hagen, S.J., und Johann Stein, S.J. Die Veränderlichen Sterne. Erster Band: Geschichtlich-Technischer Teil. Von Johann Georg Hagen, S.J. Pp. xx+811. (Freiburg im Breisgau and London: Herder und Co. G.m.b.H., 1921.) 42*s.*

Though the subject of variable stars, apart from still earlier beginnings, has been actively studied for a century, and the realisation of its importance has been reflected in a growing volume of technical literature, it has not hitherto received extended discussion on historical lines in a work exclusively devoted to this branch of astronomy. The first volume of such a work, for which Father Hagen assumed responsibility, has now been completed by the inclusion of a fourth and last part, on the elements of the light-change, the three earlier parts having been issued separately from the year 1913 onwards. The remaining second volume, which will deal with the physical explanations of the phenomena of variable stars, is in the hands of Father Stein, and its appearance will be anticipated with interest.

In these days, when the insistent demand for summaries even to the most condensed papers betrays the fact that honest reading is out of fashion, there is something impressive in an ample and scholarly work like this, with its more than 800 quarto pages. The three earlier parts dealt with the equipment of the observer, the actual observation of variable stars, and the reduction of the observations. References to other methods will be met with incidentally, but it is to the visual method in its historical development that the work is almost exclusively devoted. Naturally there are parts of the subject which are largely independent of the particular method of observation, and the discussion of them will serve a more general application.

To avoid misconception as to the nature of the work and its limitations, it will be well to refer to an explanation given at the outset in the preface. There it is stated clearly that for the principles of photometry, the practical details of astronomical photography, the description of all the various forms of apparatus and those parts of mathematical theory which are involved in the discussion of the observations, the reader must consult in each case the appropriate text-book or even an encyclopædia. To this it should be added that the book contains no figures or illustrations, and that very little space is occupied by tabular matter. Thus it is in no sense a text-book suitable for the needs of the ordinary observer, but an historical work from which the lessons of past experience can be derived from

documentary evidence. It may easily be felt that judicious compression of the abundant material, so far from diminishing, would have positively enhanced the value of the work. Moreover, while a full treatment of those technical matters, which have a general character and yet find a particular application in this special subject, would have been out of place, short explanations based on first principles could sometimes have been interpolated with material advantage to the general reader. But it is as an historical work of reference that the volume now completed must be judged, and as such it will bring the author of the "Atlas Stellarum Variabilium" the renewed gratitude of all those who are interested in this branch of astronomy. H. C. P.

The Study of Fossils.

Animals of the Past: an Account of Some of the Creatures of the Ancient World. By F. A. Lucas. Sixth and revised edition. (Handbook Series, No. 4.) Pp. xii+207. (New York: American Museum of Natural History, 1922.) n.p.

IN 1901, when Dr. Lucas was a curator of the United States National Museum, he published a most useful popular book on the study of fossils, with special reference to the remarkable extinct vertebrate animals found in North America. A decade later, when he became director of the American Museum of Natural History, New York, he reprinted his work as one of the handbooks of that museum, where it has had a large sale. He now has issued a much-revised edition, with numerous new illustrations from fossils actually in the American Museum.

Dr. Lucas's little treatise is neither a museum guide nor a text-book, but consists of a series of gossipy chapters, each on a special subject, admirably designed to rouse an interest in the study of fossils. He explains their nature, describes how they are collected and made available for science, and leaves the reader in a frame of mind to appreciate more systematic and technical works on the subject. At the end of each chapter, indeed, he refers to some of the more important literature, besides mentioning the chief American museums in which illustrative specimens can be seen.

Among the new matter may be specially mentioned a discussion of Mr. Beebe's theory of the origin of flight in birds, a chapter on flying reptiles with some good illustrations from Seeley's "Dragons of the Air," an account of Tyrannosaurus and the giant Eocene bird Diatryma, additional figures of dinosaurs, and a photograph of the restoration of the American mastodon in the State Museum at Albany. There is also a photograph of an engraved bone found in a cave near Pineville, Missouri, in 1921, which seems to show the rude outline of an elephant, either mammoth or mastodon.

Dr. Lucas writes, of course, primarily for American readers, and it is natural that he should place American discoveries in the front rank; but he is wrong in stating that "the largest single bone of a Dinosaur" is the thigh bone of Brachiosaurus at Chicago—it is three inches shorter than the humerus of the African Gigantosaurus at Berlin. The rivalry between the American palæontologists and their colleagues in the Old World is one of friendly emulation, which has led to great discoveries in more than one hemisphere.

A. S. W.

Our Bookshelf.

Methods and Experiments in Mental Tests. By C. A. Richardson. Pp. 94. (London, Calcutta, and Sydney: G. G. Harrap and Co., Ltd., 1922.) 3*s*. 6*d*. net.

IT is difficult to perceive for what type of audience Mr. Richardson's book is intended. If it is meant for readers who have no knowledge of any of the literature on the subject, then it is surely out of place to introduce the subject by a rather perfunctory discussion of the criticisms made against the use of tests. If, on the other hand, it is meant for readers already conversant with some of the work done, then much of the discussion is useless. The same remark applies to the statistical account.

The details of the experimental testing of groups of children are very interesting, but would have been more suitable for an article in a psychological journal than for a book.

The Organisation and Administration of Physical Education. By Prof. Jesse Feiring Williams. Pp. xiii+325. (New York: The Macmillan Company; London: Macmillan and Co., Ltd., 1922.) 9*s*. net.

DR. WILLIAMS urges the necessity for physical education to be placed on a scientific foundation, and gives such a basis with a wealth of detail which is rarely associated with the subject. Indeed, it is carried to an extent which, in Great Britain, is unnecessary. The chapter on health and efficiency is the least scientific; little reliance can be placed on tests involving such factors as height and weight charts, and the ratio of the girth of the arm to that of the chest. The general purpose of the book is good, and it should provide a stimulus to interest in physical education.

Character and the Unconscious: A Critical Exposition of the Psychology of Freud and of Jung. By J. H. van der Hoop. Authorised Translation by Elizabeth Trevelyan. (International Library of Psychology, Philosophy, and Scientific Method.) Pp. viii+223. (London: Kegan Paul and Co., Ltd.; New York: Harcourt, Brace and Co., Inc., 1923.) 10*s*. 6*d*. net.

THIS is a general and rather superficial account of the theories of Freud and Jung. The author tells us it is the result of nine years' intensive study of the practice and theory of psycho-analysis, which seems to mean that he has been a practitioner during that period. The translation is well done.

Letters to the Editor.

Positive Ray Analysis of Copper.

THE chief difficulty in analysing an element with a high melting-point by means of positive rays lies in the construction of a suitable furnace for evaporating the metal. I have recently succeeded in obtaining rays of copper by using a molybdenum furnace, heated with a coil of molybdenum wire embedded in alundum cement. Three isotopes were observed separated by two units in atomic weight. The relative intensities were about 1·4 : 1 : 1, the lightest being the strongest. Rays of rubidium were also obtained, probably from the cement, and showed two isotopes, as found by Aston with his method of analysis. The relative intensities gave a mean atomic weight of 85·51, in good agreement with the chemical atomic weight 85·45. To obtain agreement with the chemical atomic weight of copper 63·57, it is necessary to suppose the isotopes to be 62, 64, and 66, since this gives a mean atomic weight of 63·76, which is as close as would be expected. A direct comparison with rubidium is desirable, but further experiments will be necessary before the comparison can be regarded as conclusive, since the rubidium rays probably start at the surface of the cement and may fall through a different potential from the copper rays. A few comparisons suggested the even atomic weights, so that we may provisionally take the isotopes of copper as of atomic weights 62, 64, and 66. This seems to mark the first exception to the rule observed by Dr. Aston to hold for chlorine, potassium, bromine, rubidium, and antimony, that elements with odd atomic numbers have isotopes with odd atomic weights, and may be connected with the fact that copper occupies a place in the series of elements where the atomic weights begin to increase rapidly with atomic number.

Expansion of the Wings of Lepidoptera after Emergence from the Chrysalis.

No one who has watched a butterfly or moth emerging from the chrysalis can fail to have been impressed by the rapid expansion of the wings. This expansion is not real growth, but merely the opening out of the contents of a carefully packed parcel, and the general character of the changes which occur in the process is well known.

FIG. 1.—Pupal and extended wings of V. Jo (distance between lines = 1 inch). The pupal wings were removed from the chrysalis just before emergence.

The true growth of the wings takes place and is completed in membranous sacs just within the walls of the chrysalis, and the form of the wings can be distinguished from the outside. The position of the wings during their development is such that the upper surface of the fore wing is next to the wall of the chrysalis, and within a day or two from the time of hatching the colours and markings can in many cases be recognised.

Each wing consists of two separate membranes, united with the nervures, on which the scales are mounted, the stems of the scales entering sockets in the membranes placed in fairly symmetrical rows, though the irregular shape of the spaces between the nervures prevents the symmetry being exact.

The point to which the present note is intended to direct attention is the numerical relation between the

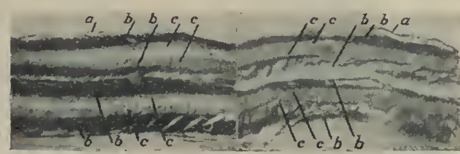

FIG. 2.—Section of pupal wings parallel to the nervures. × 60.

FIG. 3.—Section of pupal wings at right angles to the nervures. × 60.

Sections in Figs. 2 and 3 were cut from the chrysalis, and show both the fore and hind wings.

size of the pupal and expanded wings, and the reason for the constancy of this relation. In all the lepidopterous wings which I have examined the pupal wing has very nearly one-third of the dimensions of the wing of the perfect insect (Fig. 1).

If the fully developed wing is removed from the chrysalis and sectioned, the reason for the one-to-three ratio is immediately evident so far as regards extension parallel to the nervures, but the "accordion" folding whereby the scale-bearing membranes expand in a direction at right angles to the nervures is rather more complex.

FIG. 4.—Section of extended wings parallel to the nervures. × 60.

FIG. 5.—Section of extended wings at right angles to the nervures. × 60.

These sections are from the posterior part of the fore wing not far from the margin.

The section parallel to the nervures is shown in Fig. 2 and diagrammatically in Fig. 6. Here the wing membrane is seen folded so that the distance from fold to fold is the same as the depth of the fold, and therefore the extended is three times that of the folded dimension. To realise the character of folding in the other principal direction, imagine a series of camera bellows fully extended A_1A_2, etc., to be placed side by side, Fig. 9, so that the sides C_1C_2, C_2C_3, etc., will remain in contact when the bellows are contracted. Then remove the lower sides B_1B_2, etc., and join the free edges of C_1C_2, C_2C_3, etc. It is clear that the surface thus formed is developable, and that if, to start with, the bellows are compressed to one-third of their extended length the developed surface will in all directions have three times the dimension which it has when folded.

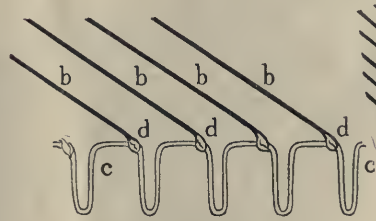

FIG. 6.—Diagrammatic section of pupal wing parallel to the nervures.

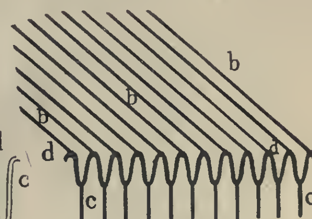

FIG. 7.—Diagrammatic section of pupal wing at right angles to the nervures.

The letters refer to those in Figs. 2 to 7.—(*a*) Wall of chrysalis; (*b*) scales; (*c*) wing membrane; (*d*) sockets in membrane.

The section of the membrane cut in this direction presents a much more complex appearance (see Figs. 3 and 7) than that parallel to nervures.

The compression to one-third of the extended dimension in the transverse direction appears to be

due to the space occupied by the "accordion" folds, and a diagrammatic sketch of the folded membrane seen in plan with the scales removed is given in Fig. 8.

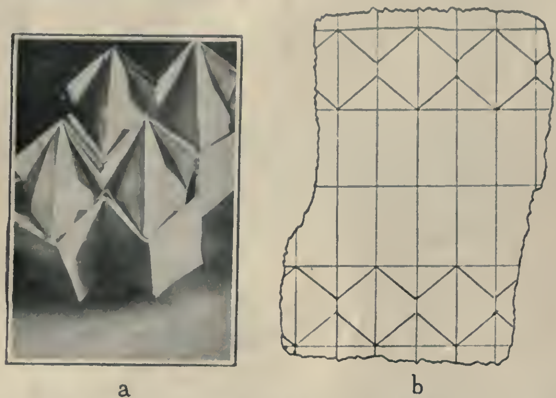

FIG. 8.—(*a*) Bird's-eye view of cardboard model showing the upper surface and side of the folds partly extended. (*b*) Developed surface of card showing the lines of folding.

The positions in which the sockets for holding the stems of the scales occur are shown at *d* in Figs. 6, 7, 8. In the pupal wing the scales are closely packed like the pile of a carpet, but after expansion lie close, and nearly parallel to the extended wing membrane, see Figs. 4 and 5.

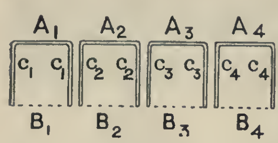

FIG. 9.—To illustrate the formation of an "accordion" folded sheet.

The mechanical means whereby the extension is effected is, I believe, of much the same nature as pumping up a pneumatic tyre, fluid being injected into the nervures by the muscular action of the body; but this is a point requiring further observation. So far as I know, it is only in the Lepidoptera that the 3 to 1 expansion occurs, but it seems probable that the same form of stiffening by injection acts in all wings supplied with nervures.

The Formation of New Egg Cells during Sexual Maturity.

IT is generally believed among mammalian embryologists that during the life of the individual there is no increase in the number of primary oocytes beyond those originally laid down when the ovary was formed. This idea has grown from two sources of evidence—one, from the Weismannian doctrine of the germ-plasm; the other, from the fact that it is difficult to find any evidence for post-natal formation of new oocytes by metamorphosis of any non-germinal ovarian cell.

The problem of the origin of sex-cells in general introduces two questions about which much discussion has taken place. The first of these questions is how the first germ cells arise; the second, whether somatic cells can change into egg cells. Many, accepting fully the work of Beard, that doyen of embryologists, and of Woods, who showed that the germ cells of certain Vertebrata originate as large pale cells of the yolk-sac endoderm, at the same time consider that the view that no somatic cell can metamorphose into a germ-cell needs more evidence than the description of germ-cell migration. Apart from this important question, some zoologists believe that no accession of new egg cells takes place during the post-natal life of any craniate vertebrate, but the evidence produced by Bouin, Braun, Ludwig, and the writer would seem to be conclusive for fish, amphibians, and reptiles.

The attached photo-micrograph (Fig. 1) of the adult frog ovary shows a large ovarian tag containing germ cells in all stages, and it is indisputable that in vertebrates below the mammals seasonal accessions of new germ cells take place.

So far as the mammals are concerned no observer within recent years has attacked the problem, but Edgar Allen in the *American Journal of Anatomy*, vol. 31, No. 5, has now published a paper in which he claims that a cyclical proliferation of the germinal epithelium gives rise to a new addition of young oocytes in the cortex of the adult ovary of Mus at each normal oestrus period. This new paper appears to me to contain the results of much careful work, and it upholds the views expressed by the Waldeyer school of embryologists.

So far as the mammal is concerned, it may be taken that since the necessity for large numbers of fresh proliferated germ cells is usually absent, these do not

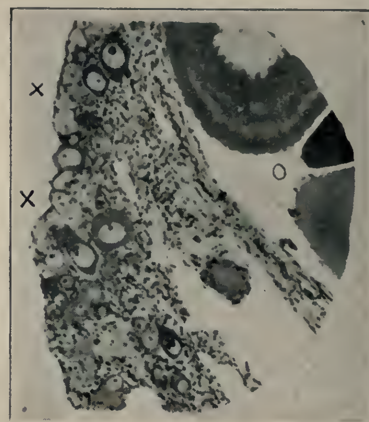

FIG. 1.—Photomicrograph of adult ovary of Rana. At X, X, are leptotene and pachytene stages of oogenesis, as well as large numbers of later oocytes. At O_1 is a part of the rest of the ovary with large eggs.

generally occur in those forms which produce few young. The writer, through the kindness of Prof. J. P. Hill, has lately examined several ovaries of Ornithorhynchus without finding any signs of oogonia in the adult: the material was not extensive enough, in the light of Edgar Allen's work, to pronounce a definite verdict, but I believe Ornithorhynchus does not produce litters of young like the rodent. It is worthy of note that Allen's descriptions of photomicrographs correspond to the descriptions and figures already given by the present writer for Rana and Bufo. Allen's Plate 5 is very striking evidence; he has, moreover, demonstrated completely the cyclical mitotic divisions and activity in the germinal epithelium of Mus.

The opponents of the germinal epithelial theory will naturally say that Allen's cells are derivatives of the migrated primitive germ cells; but unless some obvious difference can be shown to exist between the germinal epithelial cells and the forerunners of the cells described by Allen, we are justified in assuming that the new egg cells are derived from metamorphosed epithelial cells, and certainly from cells which have lost their individuality in the formation of the so-called somatic part of the ovary.

The statement, often made, that only primordial germ cells can produce gametes, and that the metamorphosis of epithelial cells into germ cells does not take place, needs also the assumption that the potential-

ities of the somatic cells are curtailed by some special cytological mechanism, which, be it marked, has not hitherto been described by any one in the Vertebrata.

The nearest approach to such a mechanism is the chromatin-diminution process in Miastor, an insect in which all but the germ cell nuclei are deprived of part of their chromatin. Nowadays, however, few zoologists wish to repeat the mistake of Weismann in deducing too much from the peculiar cytology of the holometabolous Hexapoda, which develop under special conditions. J. Origin of certain Filamentous Forms from Eocene Beds.

A PAPER by Prof. T. D. A. Cockerell has just appeared entitled "The Supposed Plumage of the Eocene Bird Diatryma" (*Amer. Mus. Novitates*, No. 62, 1923), describing certain filamentous bodies from Eocene (Green River) beds of Colorado.

Prof. Cockerell states that the specimens "are not vegetable fibres, nor are they mammalian hairs," but resemble the simple feathers of birds like the cassowary, and he refers them (with a query) to a new species of Diatryma because this is the only known Eocene bird from which they could have come.

Prof. Cockerell has been good enough to give the original of his Fig. 1B to the Geological Department of the British Museum (Natural History), and an examination of this specimen has failed to convince me that it is not of vegetable origin. Similar strands of filaments occur in Upper Eocene rocks of Haering, Tyrol, for example, and are derived from decayed leaves of palms (*Sabal major*, Ung.), into undecayed portions of which they are sometimes seen to pass. These fibres in specimens from Haering are absolutely indistinguishable from those in the original of Prof. Cockerell's Fig. 1B, and, though it is difficult to arrive at any definite conclusion from such fragmentary material, it seems quite possible that the supposed feathers may be only fibres from a decayed monocotyledonous leaf. Hafnium and Celtium.

IT is with great interest that I have read the communications of Dr. Coster and Prof. Hevesy in NATURE on the new element, hafnium. Under the title "Correlation of Atomic Structure and Spectra" (Journal American Chemical Society, xliv., p. 328, 1922) I discussed the properties of the unknown elements from the point of view of Bury's theory of atomic structure, and stated: "No. 72 possibly is Urbain's celtium. But Bury's arrangement gives the electron structure 2. 8. 18. 32. 8. 4 for this element, which is consequently tetravalent, while Urbain describes celtium as being intermediate in chemical character between Lu and Sc, both trivalent elements. A further investigation of the chemical properties and the X-ray spectrum of celtium is therefore desirable." This article was received by the editors of the Journal, November 22, 1921, and, I believe, is the first published suggestion that the chemical properties of celtium as given by Urbain do not agree with theoretical considerations of atomic structure.

Distribution of *Limnæa pereger* and *L. truncatula*.

SOME recent observations on a subject lately discussed in the columns of NATURE may be of interest. The freshwater snails, *Limnæa pereger* and *L. truncatula* are widely distributed over this district, where *Distomum hepaticum* is a serious pest: the two molluscan species occur in almost every body of fresh water where the topographical conditions are suitable, excepting only such as are seriously polluted by the effluents from old lead-workings. The hydrogen ion concentration of the fresh waters varies generally from about P_H 6·4 to P_H 6·9.

While studying a neighbouring area, a portion of the Plynlimmon plateau, about 12 to 15 miles from Aberystwyth, I was struck by the almost complete absence of freshwater molluscan species. Two only were found: *L. pereger* and *Ancylus fluviatilis*, the latter in a single locality only, the former in this and one other locality. The hydrogen ion concentrations of the waters in these two localities were P_H 6·4 and P_H 6·5 respectively: both are exceptional figures for the area, where the P_H values as a rule range from 5·8 to 6·2. (Peat bogs abound in the district.)

Laboratory experiments show that *L. pereger* invariably dies within 2 to 3 hours after being placed in water of P_H value 5·6. (Distilled water which had been exposed to the air was used for these experiments; also tap water, which has here about the same P_H value.) A characteristic reaction is given, the first phase of which is the nearly complete extension of the body beyond the shell, with violent twisting movements. Eventually the animal dies in retraction, with much exudation and coagulation of mucus. I intend before long to carry out similar experiments with *L. truncatula*. Several other freshwater species show a similar reaction, the coagulation of the mucus being especially noticeable.

Scientific Names of Greek Derivation.

IN the course of the interesting notice of Stille's "Die Schrumpfung der Erde" in NATURE of June 2, reference is made to "What G. K. Gilbert styled 'epeirogenic' (now written 'epirogenetic')." The latter termination is no doubt more correct, but the spelling of the second syllable involves a more debatable question. Some of us are by no means reconciled to the system of the Latinisation of Greek names, now widely followed, especially on the other side of the Atlantic. It is a distinct misfortune that Greek should reach the nomenclature of science by way of a language poorer in both vowel and consonantal sounds. To write "dinosaur" for "deinosaur" is to obscure the derivation of the word. So long as most of our scientific terms are derived from Greek, it is obviously desirable that they should be written in English in a form as closely similar as possible to the original, so that a student can look them up in a lexicon even if he knows but little more of the language than the letters.

I am glad, however, to see that your reviewer, when he is at liberty to follow his own predilections, prefers to adhere as far as he can to the Greek spelling. Does he not speak of "Okeanos, lord of the great outer seas"? JOHN W. EVANS.

Imperial College of Science and Technology,
S.W.7, June 4.

As the reviewer referred to, I warmly welcome the remarks of Dr. J. W. Evans on the tendency to modify Greek forms, sometimes beyond recognition, when they are introduced into scientific terminology. I went to some trouble in looking up Gilbert's "epeirogeny," which Sir A. Geikie of course spells correctly in his "Textbook of Geology." I have long clung to "deinosaur," and American authors should bear in mind that the use of an i for ei complicates pronunciation when the terms are handed on to other nations.

The chief offender, however, was Charles Lyell, who knew that he was doing wrong when he wrote his footnote on p. 53 of the third volume of the "Principles of Geology" in 1833. He justified his "Miocene" and "Pliocene" by the use of "encenia" and "icosahedron"; but the result has been the absurd American term "Cenozoic," which, if it means anything, should remind us of the emptiness of life.

The frequent use of the prefix "epi" makes one anxious to preserve "epeirogeny." I wish that we could mark the first e with a stroke to keep it long, and this remark applies also to "Tethys." But in the face of "Epirus," and "Pisistratus," and "Phidias" it is difficult to be logical. May we not attempt, however, as Dr. Evans suggests, to keep our newly invented scientific terminology from degenerating like our common speech?

GRENVILLE A. J. COLE.

On the Significance of "Rings" on the Shells of Cardium and other Molluscs.

IN NATURE of February 3, p. 146, I referred to experiments on determining the rate of growth of a fixed population of marked cockles (*Cardium edule*). In this experiment the box which was fixed in the bed of the River Yealm and contained the cockles was visited monthly, and sometimes at intervals of only a fortnight, for the purpose of measuring the increment in growth since the previous visit. This method of work resulted in an interesting observation on the formation of rings on the shells of the growing cockles. It was found that in the young cockles, *i.e.* up to about 16 mms. in length, dark rings were formed monthly or fortnightly in a majority of cases, on the shells at the size they were when last measured, but that no similar formation of rings could be detected in the larger and generally older shells. On the other hand, both small and large cockles showed distinct rings after the winter period.

In young cockles, growing in length at the rate of one millimetre or more a week, a cessation of shell-growth for a few days as a result of being taken out of their habitat and handled is enough to produce a distinct ring, but older cockles which increase *in length* a very small amount in even a month show no external sign of a small period of cessation in growth. Thus rings on the shells of cockles are undoubtedly due to periods of cessation of shell-growth, and the length of the period necessary to produce an effect depends directly upon the size of the cockle.

In this connexion it is interesting to read the history of cockles picked up haphazard. Some shells I picked up on the shifting sands of the bar at Padstow showed numerous rings close together, and there is no doubt that these rings can be interpreted as periods of cessation of shell-growth probably separated by only a few weeks, and due to the cockles being embedded deep in the shifting sand after rough weather. On the other hand, cockles picked up in protected situations show mostly those rings which can be interpreted as winter rings, but often also near the umbo, tiny rings which may mean the occurrence of a disturbance for only a few days while the individual was young. Similar winter rings have been found by experiment in Crepidula and in many cases in Patella, but Patella may not show winter rings in some situations at Plymouth after a mild winter.

In fishes the indications of periods of growth and of cessation of growth are very important, and in view of the observations mentioned above it would be interesting to know whether the otoliths and scales of *young* fishes, which show distinct rings (apparently produced in winter and summer), would reflect the effects of short periods of an analogous disturbance in the same way as the shell of the cockle.

A Crystallisation Phenomenon.

THE attached photograph (Fig. 1, natural size) is of interest, as it illustrates a phenomenon which does not appear to have been recorded.

For certain experiments it was necessary to purify some samples of salicylic acid, and recrystallisation from hot water was resorted to. The work was carried out in a litre conical flask, and a layer of crystals was formed at the surface of the solution on cooling. Below this layer many crystals were seen to be suspended by threads, and as the photograph shows, one thread would grow several crystals at different depths in the liquid.

In a bright light, reflection may occasionally be

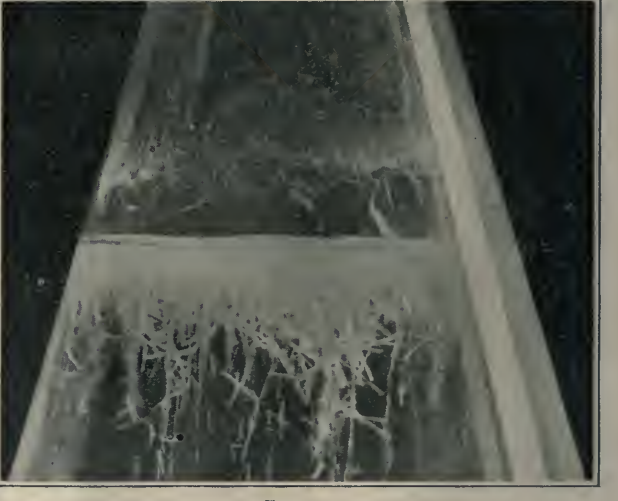

FIG. 1.

observed from some threads, but generally they are too small to be seen with the naked eye. They are elastic in the sense that, if the vessel is gently swung, the crystals oscillate at the end of their threads, which sometimes form flexible loops instead of hanging vertically. The threads are quite stable, as the suspension remains for months at a time. On one occasion the crystal layer was formed on a small grid of glass fibres and the solution syphoned out; the crystals were left hanging, but the threads could not be distinguished.

I am indebted to Mr. Sowerby of this College for the photograph.

Studies from a Wireless Laboratory.[1]

By Prof. W. H. ECCLES, F.R.S.

THE studies pursued in a wireless laboratory are mainly of two kinds: first, those directed to the solution of problems that have arisen in the development or use of practical apparatus, and, secondly, those with which we are here concerned, aiming at the application of novel principles or novel physical phenomena to the invention of new methods or apparatus. Little will be said of the methods of wireless communication as they exist to-day; on the contrary, our attention will be devoted to some possibilities of wireless telegraphy—possibilities tested in the laboratory but not yet tried on the large scale. In other words, no attempt will be made to give a record of technical progress accomplished to date but, rather, to discuss wireless communication as it may be.

The new methods to be first described are based upon the phenomena, not yet fully known in detail, which occur when one vibrating body is caused to influence the vibrations of another. Consider the case of a simple pendulum consisting of a weight tied to the lower end of a string the upper end of which is held in the hand, and suppose it is of such a length that it would vibrate freely to and fro in a period of two seconds, when the hand is held still. Then it is easily

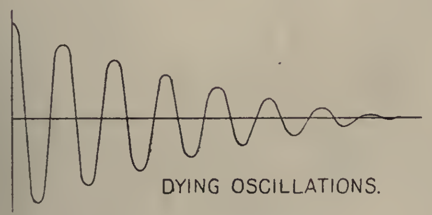

FIG. 1.—Dying oscillations.

seen that on moving the hand horizontally to and fro with a complete period of, say, one second, the pendulum will follow the hand and likewise vibrate with a period of one second. Similarly, when the hand vibrates with a period of, say, three seconds the pendulum will again follow and take the new period. This experiment is very familiar and is known to students of mechanics as an example of the subject of "forced vibration."

A pendulum forced in this manner may be said to vibrate "in time with" the hand, but the experiment shows that it is not "in step with" the hand. It would not be correct to say that it is "in tune with" the hand, since this term is reserved—in electrical physics at any rate—to indicate that the natural period of the free and unpropelled pendulum is the same as the period of vibration of the hand. We may, however, express the state of affairs by saying that the pendulum is forced into accord with the hand and that it is then in the "accordant state." A simple example of this relationship between two alternating movements is seen when a dog, for example, is walking along the road; his hind legs are in time but not in step with his fore legs.

The vibrations of a simple pendulum left free to vibrate with its own period gradually die down as indicated in Fig. 1. The vibration is a dying oscillation, and in such a case the theory of the forced vibrations is easily understood. In a modern wireless laboratory, however, we have to deal with growing and sustained vibrations as in Fig. 2, and in such cases the theory of the accordant state is rather different. This is to be expected—for it is like comparing a living thing to a dying one. Usually the vibrations are sustained by the aid of the triode valves so well known, and the rates of vibration are very high. In order to lead up to an understanding of the accordant state at these high frequencies it is best to study low frequencies first.

For the study of vibrations slow enough to be followed

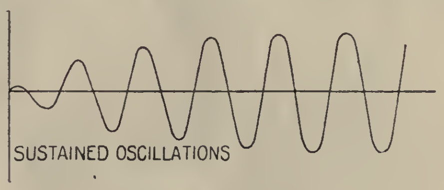

FIG. 2.—Growing and sustained oscillations.

by the eye a new type of oscillator has been designed and constructed and is here exhibited for the first time. Fig. 3 is a diagrammatic plan of the apparatus. The horizontal magnet has a horizontal ebonite rod fixed to it at right angles and the whole is suspended from a vertical torsion wire passing through the centre of gravity. The poles of the magnet confront two horizontal solenoidal coils connected in series with each other and with a battery and diode valve, that is, a thermionic valve of the type invented by Prof. Fleming in 1904 and containing only two electrodes, namely, a filament and a plate. Such a valve possesses the

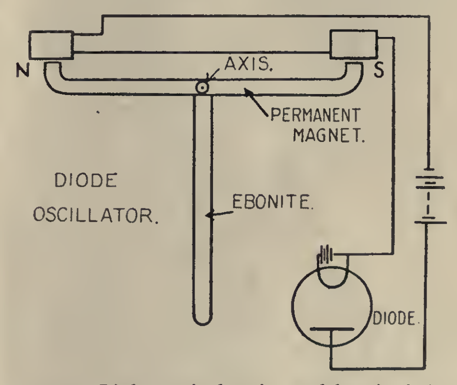

FIG. 3.—Diode-sustained torsion pendulum (in plan).

property that the electron current across the vacuum is sensitive to outside electrical influences if the electrodes have suitable relative positions—an ebonite rod charged by rubbing causes a diminution of the electron current when it approaches the diode and allows the current to increase again when it recedes. The action of this diode-sustained pendulum is now easily explained by supposing it swinging, and noticing that the ebonite rod as it moves to and from the diode causes an alternation of magnitude of the currents in and magnetic fields of the coils, which is automatically in correct time relation

[1] Substance of a discourse delivered at the Royal Institution, Friday, April 13.

to assist the motion of the magnet. By means of a small mirror fixed to the magnet, and a lamp and scale, the building up of the motion from a small initial amplitude is easily seen.

With two such pendulums the accordant state can be studied by eye observation. Dr. Winifred Leyshon is engaged upon this task. As arranged for the investigation one of the pendulums is made the master by sending some of its current through an auxiliary winding influencing the magnet of the other pendulum. The frequency of either the master or of the servant pendulum can be varied by the aid of a movable permanent bar magnet placed near the oscillating magnet. Then it is seen that as one natural period becomes nearly the

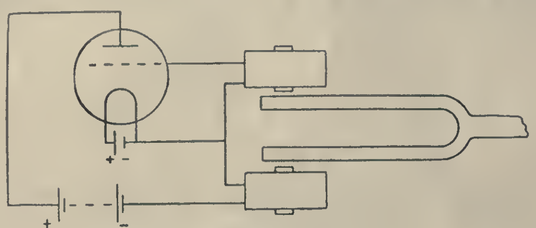

Fig. 4.—Triode-sustained tuning-fork.

same as the other the master catches hold of the servant, compels it to abandon its own natural period and to move in time with the master's—though not necessarily in step. The amount by which the servant is out of step depends upon the difference of the natural periods and therefore can be regulated.

These slow vibrations are seen and not heard ; but it is also possible to use vibrators of acoustic frequency and so make the according process evident to the ear. A tuning-fork sustained by a triode is very effective as the master oscillator. The circuit is shown in Fig. 4, from which it will be seen that when the fork is vibrating the induced electromotive force acting upon the grid controls the anode current so as to sustain the motion.

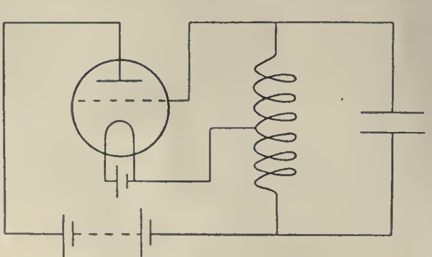

Fig. 5.—Triode electrical oscillator.

(See Eccles and Jordan, "Sustaining the Vibration of a Tuning-fork by a Triode Valve," The *Electrician*, June 20, 1919.)

On the other hand, an electrical oscillation, which is independent of moving matter, makes a good servant oscillator. Its circuit is shown in Fig. 5. The linkage between the two oscillators is effected by passing some of the current from the fork coils through an auxiliary winding on the electrical oscillator. The fork is audible when oscillating because it agitates the air; the electrical oscillations can be made audible by inducing currents in another circuit containing a loud-speaking telephone, and their frequency can easily be altered through a semitone or more by varying slightly the capacity of the condenser shown in Fig. 5. Now, as the natural frequency of the electrical oscillator is made to approach that of the fork, loud throbbings (called "beats") are heard, which become gradually slower until at a certain point the master suddenly drags the servant into time and the throbbings cease. If the movement of the condenser is continued the natural period of the electric oscillator is carried through resonance and then beyond, and finally the servant breaks away from the master and the throbbings indicating their difference of frequency begin anew.

This experiment is reminiscent of that of the two air-blown organ pipes discussed by the late Lord Rayleigh many years ago (*Phil. Mag.*, 1879, Collected Papers, vol. i. p. 409). Rayleigh showed that two organ-pipes nearly in unison dragged each other into a common frequency if brought into propinquity.

The preceding experiments have carried us from vibrations at 2 per second to vibrations at 200 per second ; we now pass to the problem of accordance when the vibrations are of frequency 200,000 per second, such as are commonly used in wireless telegraphy and telephony. Such high frequencies are neither seen nor heard, but can be detected by special methods. The electrical oscillator nsed comprises a triode and an inductance and capacity connected as in Fig. 5 and chosen of suitable magnitudes. The detecting apparatus is an inductance coil and variable condenser connected to a crystal detector just as in many a household crystal apparatus used for listening to the broadcasting stations. A galvanometer is connected to the crystal and a spot of light moves on the screen when the condenser is varied while the triode apparatus is in action. A maximum deflexion is soon found and then the receiver is in tune with the triode oscillator. Another triode oscillator is now substituted for the first and varied in frequency until in tune with the crystal receiver. Clearly both triode oscillators are now of approximately the same frequency. Let them both be put into action simultaneously so as to act upon the crystal circuit, and let a pair of auxiliary coils, connected in series, be placed confronting the respective triode oscillators in order to establish a linkage. The crystal circuit is receiving energy from both of the triode oscillators and actuates the galvanometer. The accordant state is then easily found by varying one of the oscillators very slowly and watching the spot of light. At the moment when the two oscillators come within a certain frequency difference, they suddenly pull into time and the spot of light gives a sudden kick. This phenomena was discovered by Dr. J. H. Vincent and described in the Physical Society Proceedings (p. 84, Feb. 1920). One of his curves is reproduced in Fig. 6.

This curve illustrates that as the condenser of one triode oscillator is increased the galvanometer in the crystal circuit shows first an increase and then a very sudden decrease of deflexion. The nearly vertical parts of the curve are due to the establishment of accordance. In a rough way one may explain the phenomenon by saying that at the lowest point of the curve, where there is a sharp cusp, the two oscillators though vibrating in time with each other are oscillating oppositely. In fact one oscillator is moving like the front legs and the other like the hind legs of the dog cited already. The curve or the experiment shows that

a very minute variation of the condenser of either oscillator makes the deflexion increase enormously.

There are several ways of applying this novel phenomenon to wireless telegraphy. Two of these may be illustrated here. Suppose one of the two oscillators to be a distant transmitter from which electric waves are proceeding, and that these waves are picked up by the antenna at a receiving station. Let the antenna be coupled to a local oscillator in the relationship of master, and let a tuned detector circuit be acted upon by both the antenna and the local oscillator. Then suppose the local oscillator adjusted until it is in the accordant state with the antenna oscillations, and, in fact, adjusted until the detector current is at the minimum value corresponding to the cusp of Vincent's curve (Fig. 6). It then follows that a very minute variation of the frequency of the oscillations emitted by the distant station will give rise to a deflexion of the galvanometer. It is suggested that signals could be transmitted by up and down changes in frequency—such changes would be far smaller than the changes of frequency employed by the accepted methods of the present day, and thus the interference between stations

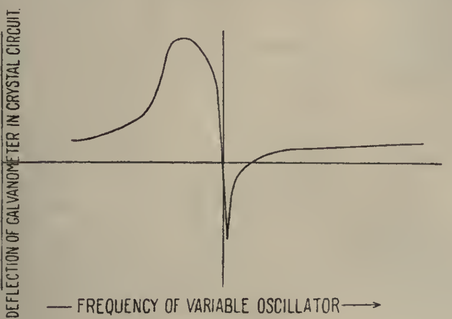

FIG. 6.—Vincent's curve.

would be minimised. There are many easy ways of producing small changes of frequency at the transmitting station.

Another and very different method of signalling may be illustrated by this same apparatus, after again adjusting the receiving apparatus to the minimum deflexion obtained in the accordant state. On trial it is found possible to bring the spot of light to any desired point of the scale—that is, to any desired point on the vertical portion of the Vincent curve—by appropriate adjustments of the frequency of the transmitting unit. These latter adjustments are for this purpose conveniently effected by the motion of a short circuited coil of wire near the inductance coil of the transmitting oscillator. Therefore, to every position of the auxiliary movable coil at the transmitter there corresponds a position of the spot of light actuated by the receiving apparatus. It might even be possible to mark the scales at each place with an alphabet and so communicate intelligence without the aid of the Morse code.

The above-described methods of signalling are based on the discovery of accordance between triode oscillators. Another distinct series of methods can be suggested and illustrated. These methods depend on the fact that the combination of two high-frequency electrical vibrations of slightly differing frequencies yields a throbbing amplitude which may be made of audible frequency and of any desired pitch by adjusting the frequency of either of the original vibrations. The formation of relatively slow throbbings from two quicker oscillations is shown diagrammatically in Fig. 7. The existing modern method of receiving continuous waves known as the heterodyne method utilises this principle in the following way: The transmitting station emits long and short trains of waves

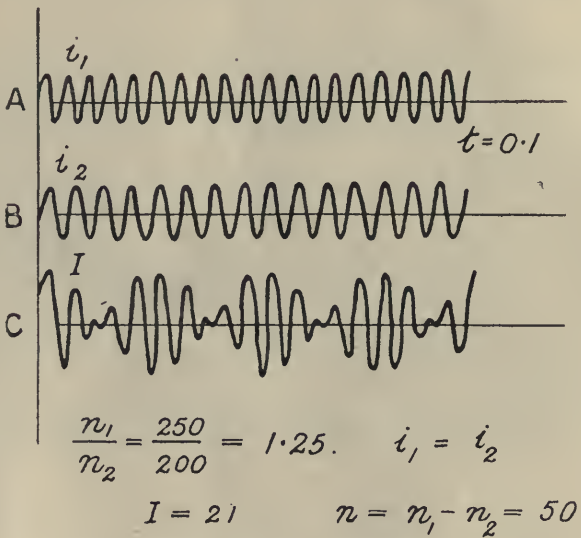

FIG. 7.—Illustrating the heterodyne method of reception.

corresponding to Morse dashes and dots and of frequency, say 200,000 per second. These waves produce in the receiving antenna feeble oscillations which are combined with locally generated oscillations of about the same strength and of frequency, say, 200,500 per second. The result is a compound high-frequency current with 500 throbbings in it per second. These when rectified can be heard in a suitably connected telephone. The long and short trains of waves from

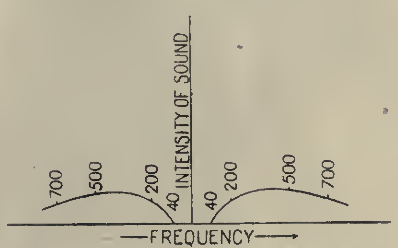

FIG. 8.—Diagrammatic representation of sounds heard in heterodyne reception.

the transmitting station thus give rise to sounds of long and short duration and of constant pitch. The pitch is adjustable by altering the local frequency from 200,500 to other values.

By altering this frequency from, say, 199,300 per second to 200,000 and then to 200,700 the sounds in the telephone run through a continuous scale of notes as represented in Fig. 8. This starts on the left with a note of 700 which falls in pitch to about 40 and becomes inaudible, passes through resonance, becomes audible again, and ascends a scale in opposite order to the first

scale. Thus a note of any desired pitch can easily be obtained, but the intensity varies on account of the varying sensibility of the ear and the apparatus. This possibility of variation of pitch makes a number of new methods of wireless signalling feasible. One of the easiest resembles a very early kind of moving needle telegraph apparatus called Bright's bells in which the needle moved to one side and struck a bell in order to indicate a dot and moved to the other side and struck a bell of different tone to indicate a dash. This method was faster than the dot and dash sounder and apparently easier to learn. In its proposed wireless form the transmitting station would emit equal wave trains to represent dots and dashes, say of 200,200 frequency to represent the dots and 200,500 frequency to represent the dashes. Each Morse sign is then heard as a little melody at a receiving station using a local oscillator of 200,000 frequency. Besides the advantage mentioned above there is a likelihood that these signals would be less distorted by atmospheric discharges than are longs and shorts of constant pitch.

Still another simple method consists in utilising three very close high-frequency oscillations at the transmitting station, say 200,200, 200,100 and 200,050, and making a new code for the alphabet out of permutations of these. The local oscillator would have a frequency of 200,000, and therefore the sounds heard in the telephone would be short tunes. The method would be faster than Morse, but might demand that the operators should have musical ears. Still another method can be imagined in which chords of three notes instead of arpeggios are used for the letters of the alphabet, but this might require an even more musical ear.

But there is one kind of chord which every one can recognise without special training, which even the horse can discriminate in the sounds of "whoa" and "gee." The vowel sounds are in fact chords. Lately Sir Richard Paget has given (Vowel Resonances, International Phonetic Association) a list of the chief tones occurring in the English vowels. For example, the vowel sound in the word "calm" contains the tones of frequency 1360 and 810 per second. Suppose, therefore, a transmitting station is arranged to emit simultaneously electric waves of frequencies 201,360 and 200,810, and suppose these waves when received at a great distance are combined with local oscillations of frequency 200,000 per second. Then the tones 1360 and 810 are perceived simultaneously as a chord in the operators' telephones. But this chord by itself is scarcely if at all recognisable as a vowel. Recognition is ensured by superposing a larynx note by aid of a buzzing contact included in the receiving circuit. Then whenever a train of two waves leaves the sending station the vowel is pronounced by the receiving apparatus. This is easily illustrated to an audience by the aid of a loud-speaking telephone. Lecture apparatus for producing and detecting the two vowel sounds represented by *o*, *a*, is shown in Fig. 9. The change of

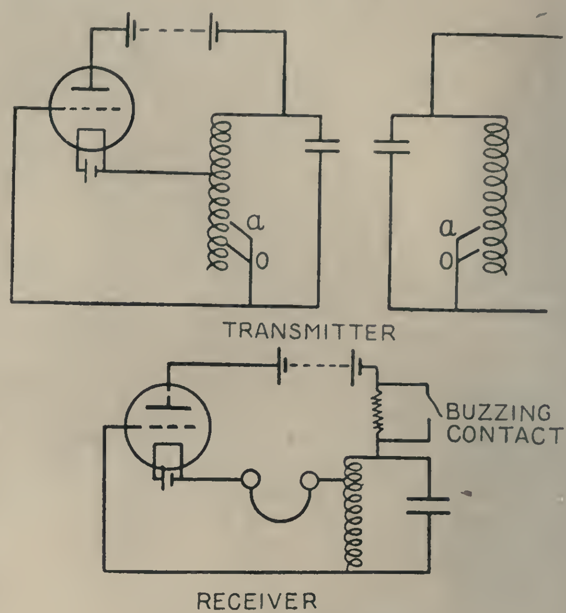

Fig. 9.—Heterodyne vowel apparatus.

radio frequency necessary for passing from one vowel to another is provided by the tappings on the inductance coils. In this apparatus the transmission occurs across a short distance; in practical telegraphy the transmitter would be more powerful and would be provided with an aerial and the receiving apparatus would also have an aerial.

The apparatus, which was built and made to work by Messrs. C. F. A. Wagstaffe and E. S. Smith, two former Finsbury Technical College students, was constructed to produce six vowels, namely, those heard in the words eat, all, hate, shoe, calm, and earth. These six vowels taken in pairs yield thirty-six symbols which, together with the five vowels *a, e, i, o, u* representing themselves, amount altogether to forty-one symbols. An alphabet formed in this manner is much briefer than the Morse code; that is to say, there are fewer efforts of the sending key in making the same message. For example, in the word London there are seventeen efforts when Morse is used but only eight when the vowel code is employed. Besides the gain in speed there is a possibility of reception through atmospheric disturbances being more easily accomplished with the vowel code than with the customary dots and dashes of constant pitch, but this can only be tested by actual trials.

Ur of the Chaldees.

By C. Leonard Woolley.

In 1919 Dr. H. R. Hall, on behalf of the British Museum, spent three months excavating at Ur. Last summer the British Museum and the University Museum of Philadelphia decided to send out a joint expedition which should continue for a term of years the work begun by Dr. Hall, and clear as much of the site as seemed likely to repay the necessarily heavy cost of a scientific mission. The first season's work of the joint expedition is now over, and the results amply justify the confidence of those who promoted it, and give every promise of even greater success in the future.

Mesopotamian sites are often on a very large scale, and though Ur cannot compare in this respect with Babylon, yet the mounds of the ancient city, spreading in length for some three and a half miles, afford a rather bewildering scope to the excavator. At Babylon, in the course of their eleven years of work, the Germans excavated a number of the most prominent mounds, with excellent results; but there is this drawback to the system, that we have in consequence a number of important buildings or groups of buildings isolated from one another, and can deduce from them very little regarding the lay-out of the town plan. At Ur it will take many seasons to obtain anything like a plan of the whole city, but luckily we are, even thus early in the day, able to learn a great deal about the most important element in the city—the "temenos" or sacred area wherein lay the principal temples and the palace of the king.

Dr. Hall had dug one section of the wall which enclosed this temenos. Last season we traced it for nearly its whole circuit and cleared four out of the six gates by which it was pierced. Inside it the great ziggurat or storied tower of brick is unmistakable, forming, even in its ruined state, a landmark visible for many miles. Dr. Hall excavated part of a building which we have identified as the sanctuary of the great temple of the Moon-god Nannar (the greater part of it has still to be dug). We have completely cleared a smaller temple dedicated to the Moon-god and his consort; and we have been able to fix with tolerable certainty the position of two other temples and of the royal palace. Already, therefore, we know not a little about the topography of the temenos; and as by means of air-photographs we have been enabled to trace, without digging, much of the main outer wall of the city, the problem of where work can most fruitfully be done is simplified to an unusual extent.

The temenos wall was built, as numerous clay dedication-cones inform us, by Ur-Engur, the king who founded the Third Dynasty of Ur about 2300 B.C. It is a hollow or compartment-wall, each wall being over 9 feet thick with 13-foot chambers in the interior. Built of unbaked mud brick, its face relieved by vertical double-rebated grooves, it still stands in places nearly 10 feet high (Figs. 1 and 2). But the existing brickwork is by no means all of the founder's date. Often in its long history it was patched or rebuilt, and in the gateways (where of course repairs were most frequently required) we find records of later restorers dating from Ur-Engur's own grandson, Bur-Sin, to Nebuchadrezzar, king of Babylon (600 B.C.), and Cyrus of Persia (*c.* 535 B.C.). Soon after Cyrus's time, perhaps in the middle of the 5th century, the temenos wall, with all the temples which it enclosed, was destroyed by Zoroastrian iconoclasts. In one of the gateways, last restored by Nabonidus, Cyrus's predecessor, the scorched brickwork and the charred beams of the gate-chamber roof survived as a testimony to religious intolerance. It was just inside this gateway that we found a headless diorite statue of Entemena, king of Lagash and of Ur about 2900 B.C.; it is probable that this ancient and already mutilated figure was unearthed by Nabonidus, who had a passion for archæology, and set up on the ziggurat in front of the gate.

FIG. 1.—Part of the buttressed outer wall of E-nun-makh, the temple of the Moon-god and his consort. The lower part was built by Bur-Sin (2250 B.C.), the upper part by Kudur-Mabug (2000 B.C.): the interior brickwork seen above is by Nabonidus, last king of Babylon (*c.* 550 B.C.). By courtesy of the trustees of the British Museum and the Board of the University Museum, Philadelphia.

FIG. 2.—Room in the sanctuary of E-nun-makh, the temple of the Moon-god and his consort, showing the old walls, the new floor of bricks laid by Nebuchadrezzar, the side altar with its offering-table, and the groove in the floor for the "chancel screen." By courtesy of the trustees of the British Museum and the Board of the University Museum, Philadelphia.

The temple of the Moon-god and his consort was a foundation far older than the temenos wall. When Ur-Engur repaired it, as he did, it had already been twice rebuilt, and the original builder is lost to us in the mists of antiquity. That the temple was in use by 2650 B.C. we know, for we found in it fragments of decorative stone vases dedicated by kings of Agade at that time—but probably it was venerable enough then (Fig. 3). Bur-Sin, the second in descent from Ur-Engur, thoroughly rebuilt the place; so did Kudur-Mabug (about 2000 B.C.) and Kuri-Galzu (four hundred years later); but then, and until another thousand years had passed, the form of the temple remained the same: like a human body regularly renewing its tissues, the old building was still itself though its bricks changed. So careful were the royal builders to keep to the old times that, as a rule, each left one or two courses of his predecessor's building *in situ* to serve as a guide to the new bricklayers, and as a result the lower parts of the walls which survive to-day sandwich into a few feet successive periods of history covering two and perhaps three thousand years. Nebuchadrezzar was the first to embark on a radical alteration. The original five-roomed sanctuary had been private, the god's own house, hidden away behind priests' chambers and stores and approached only by a winding passage. Nebuchadrezzar did away with all the service-rooms in front of the door, substituting for them a wide-open court with a smaller upper court whereon stood the altar. The alteration clearly points to a change from a secret ritual to public or congregational worship such as that referred to in the Bible story of the Three Children.

FIG. 3.—1, Votive alabaster mace-head of Ur-Engur (2300 B.C.). 2, 3, Votive alabaster mace-head and vase of Rim-mush, King of Agade (2650 B.C.). By courtesy of the trustees of the British Museum and the Board of the University Museum, Philadelphia.

The number of objects found in the course of the excavations was very great, including jewellery of the Neo-Babylonian and Persian periods, ivories and bronzes, hundreds of inscribed tablets, mostly of the time of the Third Dynasty (2300–2000 B.C.), terracotta reliefs, carved and inscribed stone vases, pottery, glass and stone beads, etc., etc. A special exhibition of these will be arranged at the British Museum as soon as possible, and illustrated lectures describing the progress of the excavations will also be given.

Current Topics and Events.

THE present outbreak of small-pox in Gloucester is very different from the tragedy of 1895–96. The number of cases in that frightful epidemic was 1981: and the number of deaths was 434. On the present occasion, the number of cases, up to now, has been about one-tenth of that number. As in other places, so in Gloucester, a very mild type of small-pox has appeared: indeed, so mild that, to some people, the very nature of small-pox seems to have changed. Still, the possibility remains that the disease will, some day or other, recover its old virulence. Besides, it appears that some of the Gloucester cases have been serious. Thus, at a meeting of the city council on June 27, the Mayor spoke of "some of the fearful sights" in the wards of the Isolation Hospital, and said that he should never forget them: and the chairman of the Health Committee spoke of "severe and ghastly" cases in the same hospital. Unhappily, so mild were the first cases that they were mistaken for chicken-pox. The best authority on the rules for avoiding this mistake between small-pox and chicken-pox is Dr. Wanklyn: and his writings are worth reading. The mildness of the epidemic, the controversy over its nature, the frequent concealment of cases, and the work of the anti-vaccinationists, have brought about a most unfortunate state of affairs in Gloucester. The fear is that Gloucester is steadily exporting small-pox to neighbouring towns.

THE first presentation of the Paterno medal was made on July 19 during the meeting of the International Union of Pure and Applied Chemistry in Cambridge. The chairman, Sir William Pope, explained that subscriptions had recently been collected to form a foundation to commemorate the many contributions made to chemistry in so many of its fields by Prof. Emanuele Paterno. It had been decided that the memorial should take the form of a gold medal to be awarded every three years for the most noteworthy discovery made in chemistry. Prince Ginori Conti, the president of the Italian Chemical Society, announced that at a recent meeting in Rome the committee appointed had unanimously nominated Dr. F. W. Aston as the recipient of the first award for his work in theoretical chemistry in connexion with the mass-spectrograph and isotopes. Prof. Paterno then presented the medal. Dr. Aston in replying expressed his sincere thanks for the great honour done to Cambridge and to himself by the award. He emphasised the importance of such international prizes as promoting goodwill between nation and nation, and expressed the hope that the distinguished chemist who made the presentation would be spared to assist at many similar occasions in the future. Although the work for which the award was made was almost entirely physical, he reminded the chemists present that his first published researches were in the domain of organic chemistry, and that to-day all definite distinction between physics and chemistry had been swept away by the discovery of the electrical constitution of matter.

NEWS of Mr. K. Rasmussen's researches in Arctic Canada have been published in the *Times* in a dispatch written in December 1922. The east coast of Melville Peninsula from Repulse Bay to Fury and Hecla Straits was charted, and extensive studies were made of the little-known Eskimo tribes in that region. These tribes, the Aiviliks and Igdluliks, have been largely influenced by the whalers who used to visit the coast in the latter half of last century. The whalers took the Aiviliks into their service as boatmen, finding them far superior for this purpose to the Eskimo of Greenland. The result was that the kayak fell into disuse and there are now no kayaks on this coast. Hunting sea animals plays a small part in the lives of these Eskimo, and the use of modern hunting gear, which alone is employed, will die out with the disappearance of the men trained by the whalers. Seal-hunting is not widely pursued, and consequently there is a shortage of blubber. In winter the snow huts are generally unheated, and Eskimo have to rely on good furs for warmth. Mr. Rasmussen found them hardy to an incredible degree. During summer many families move inland for trout-fishing and reindeer-hunting, but reindeer are scattered and not numerous. Hunting begins in July or August, which is the earliest time that the skins are fit for clothing. During the present summer Mr. Rasmussen, with one Eskimo companion, proposed to travel across Arctic Canada to Alaska and over Bering Strait to visit the Eskimo in Siberia. Other members of his expedition were to study the tribes of Melville Peninsula, and cross the interior of Baffin Land to the Hudson Bay Co.'s post on Home Bay. The result of all these researches promises to elucidate the problem of Eskimo origins.

ON Monday, July 2, the Prince of Wales opened the new anatomy, biology, and physics department of Guy's Hospital Medical School. The new building, which completes the rebuilding scheme started some twenty-seven years ago, consists of five floors. It provides accommodation for the teaching of embryology and histology in connexion with anatomy and for surgical research work, while close at hand is the new biology department. The transference of the physics department to the new building has provided increased space for the organic and biochemical side of the chemistry department.

THE twenty-fifth anniversary of the graduation, *honoris causa*, of Prof. F. A. H. Schreinemakers in the University of Leyden on July 7 is being marked by the issue of a special number of the *Recueil des travaux chimiques des Pays-Bas* which will contain more than sixty articles in English, French, German, and Italian by various colleagues, pupils, and friends, in Holland and elsewhere, of Prof. Schreinemakers. Copies of this number (price 8*s*. 6*d*.) can be obtained from Miss W. C. de Baat, Leyden (Holland), Jan van Goyenkade 30.

ACCORDING to the *Chemiker Zeitung*, Prof. A. Einstein has been elected a member of the order Pour le Mérite.

LORD CRAWFORD AND BALCARRES has been elected a trustee of the British Museum, in succession to Lord Rosebery, who has resigned.

IT is stated by the Ottawa correspondent of the *Times* that the Canadian Parliament has unanimously voted an annuity of 1500*l*. for Dr. Banting, the discoverer of the insulin treatment of diabetes, to enable him to carry on his scientific work.

THE French Association for the Advancement of Science is holding its annual meeting at Bordeaux on July 30-August 4. Communications regarding the meeting should be addressed to the secretariat of the Association at 28 rue Serpente, Paris, 6e.

PROF. F. GOWLAND HOPKINS has been awarded the gold medal of the Royal Society of Medicine, which is given triennially to a scientific worker, man or woman, "who has made valuable contributions to the science and art of medicine."

AT a meeting of the Royal Society of Edinburgh held on July 2 the following foreign honorary fellows were elected: Prof. E. B. Wilson, professor of zoology, Columbia University, New York; M. M. Boule, director of the Institute of Human Palæontology, Paris; Prof. A. F. Holleman, professor of organic chemistry at the University of Amsterdam; Dr. A. A. Noyes, Institute of California, Pasadena; Prof. T. W. Richards, professor of chemistry, Harvard University, Cambridge, Mass.; Prof. Tullio Levi-Civita, professor of mathematics (higher analysis) at the University of Rome; Prof. Henri Bergson, honorary professor of the College of France; and M. Alfred Angot, late director of the Central Bureau of Meteorology, Paris.

AT the annual general meeting of the Röntgen Society on June 5, the following officers were elected :—*President* : Sir Oliver J. Lodge ; *Vice-Presidents* : Sir Ernest Rutherford, Dr. A. E. Barclay, and Dr. F. W. Aston ; *Hon. Treasurer* : Mr. G. Pearce ; *Hon. Editor* : Dr. G. W. C. Kaye ; *Hon. Secretaries* : Dr. E. A. Owen, Mr. R. J. Reynolds ; *Council* : Mr. C. Andrews, Dr. G. B. Batten, Lt.-Col. Kenelm Edgcumbe, Mr. N. S. Finzi, Mr. W. Hope-Fowler, Dr. F. L. Hopwood, Dr. J. E. A. Lynham, Mr. G. H. Orton, Prof. A. W. Porter, Prof. S. Russ, Dr. R. W. A. Salmond, and Mr. W. E. Schall.

IN the report of the council of the British Medical Association it is stated that the British Medical Association in Australia has instituted a gold medal for the purpose of perpetuating the appreciation of services rendered by members of the British Medical Association in Australia. The medal has on one side the figure of Æsculapius in relief, and on the obverse a wattle wreath, with the wording "The British Medical Association in Australia," "For Distinguished Service," with loop and ribbon of royal blue. It is to be presented at the congress of the British Medical Association in Australasia to be held in Melbourne in November, and the first recipients will be Dr. R. H. Todd and Dr. W. T. Hayward.

A SUCCESSFUL "commemoration day" was held at Livingstone College on June 13, Sir Leonard Rogers being in the chair. Various speakers testified to the benefit of the training received at the College, which is designed to give to missionaries the elements of medical knowledge. The College would be self-supporting if a sufficient number of students were sent to the College regularly, but at present this is not so, and about 500*l.* is urgently needed.

THE Marlborough College Natural History Society has long been prominent in maintaining an interest in field-studies, and through them in the essential beauty of the earth, among those who otherwise might grow up on the old conventional lines of public-school education. The report for 1922 (Marlborough : the *Times* Offices, 1923) records the proceedings of a number of sections, including those of astronomy and archæology ; the latter is carrying out actual excavations on the site of Castrum Merlehergæ (pp. 37-45). The botanical section has added two new species to the local list during the year. Perhaps the most striking signs of activity are the geological excursions taken in Scotland, during which the members were very kindly guided by Mr. G. W. Tyrrell, lecturer in the University of Glasgow, over ground dealt with in his own researches. Mr. A. G. Lowndes (p. 57) gives a lucid account of the conditions under which the pitchstones of the dykes in the Isle of Arran were formed, and this is accompanied by a plate of thin sections as seen under the microscope. The other photographic illustrations, including birds' nests in their natural surroundings, add much to a stimulating production. We are sure that members of this firmly established Society carry the memories of its field-days to their more ambitious journeys on *safari* in Kenya, or in dug-outs on Malayan seas.

THE University of Chicago Press, Chicago, Illinois, has just issued a third edition of its very useful illustrated catalogue of astronomical photographs. The photographs have been reproduced mainly from negatives taken at the Yerkes Observatory, and have been issued for the convenience of the general public, the man of science, the student, and the lecturer. They comprise lantern slides, transparencies, and prints, issued at uniform prices ; but, at an extra cost, they may be obtained modified in size or other qualities, to meet individual needs. Card descriptions of the lantern slides also are published. The photographs appear to cover the whole range of observational astronomy, and include, in addition, a number of views of astronomical instruments and portraits of famous astronomers of the past and present. There are, finally, a few stereograms, chiefly of the moon, planets, and comets. A large number of the photographs were taken by the late Prof. Barnard, among which his well-known and beautiful pictures of the Milky Way and of dark markings in the sky are particularly welcome. Of great value to teachers and lecturers are the photographs of stellar spectra, with terrestrial comparison spectra, illustrating the Doppler displacements due to relative motion of the star and the earth in the line of sight. Reproductions of two of these photographs are given in the catalogue ; they show the effect with unusual clearness and beauty. It would have been a great boon to teachers of astrophysics if the publishers had found it possible to include a complete series of typical spectra, in the visible region, of the various Harvard types. Only the violet and ultra-violet regions are now accessible. The catalogue should prove extremely useful to all who are interested in any way in the observation of the heavens.

THE Manila Weather Bureau sets a praiseworthy example to many larger institutions in the comparative promptness—judged by post-War standards—with which it issues its volume of magnetic observations for the calendar year 1919. Until 1904 the observatory was at Manila, whence it had to be removed, on account of electric tramway disturbances, to Antipolo, twelve miles distant from the city. It started its new career in 1911, and its annual reports have since then been modelled on the pattern adopted by the U.S. Coast and Geodetic Survey. Hourly values of declination and horizontal and vertical magnetic force are given, together with the daily mean, maximum, minimum, and range for each element. Mean diurnal inequalities are given for each month and for the five quietest and five most disturbed days per month. These inequalities are also summarised in separate tables : the inclusion of a table of daily variation of the total force might perhaps be dispensed with.

A USEFUL pamphlet published by the United States Coast and Geodetic Survey (Special Publication No. 93, price 30 cents) deals with Reconnaissance and Signal Building. The author, Mr. J. S. Bilby, writes from experience of actual cases arising in the routine of field work, and dwells on the practical

difficulties that are encountered in a preliminary reconnaissance for precise triangulation. The first part of the publication discusses the character and strength of triangulation figures, selection of sites, and intervisibility of stations. The second part deals with signal building, and includes practical directions, with detailed plans and specifications. The section on hydrographic signals is specially interesting. Signals of some kind or other, either ashore or afloat, are frequently necessary in the location of soundings off a low flat coast. Full plans and illustrations and a note of the amount of material required are given.

THE third number of volume i. of the *Japanese Journal of Botany* has just been issued by the National Research Council of Japan. In addition to botanical papers, it contains reviews of the current Japanese botanical literature, much of which is published only in Japanese and has hitherto been unavailable to workers in other countries. This is therefore a valuable feature of the Journal, and should be of much service in making more widely known the work of Japanese botanists. The present number contains papers in English and German, chiefly on genetical subjects, as well as abstracts of the principal botanical papers which have appeared in Japan during the period April-September 1922.

M. MARCELLIN BOULE, the eminent French anthropologist, in the Huxley Memorial Lecture for 1922, published in the Journal of the Royal Anthropological Institute (vol. lii., 1922), describes the services rendered to the study of man by the late Prince Albert I. of Monaco. The Prince, impressed by the importance of the remarkable cave records in southern France, devoted much attention to the development of these discoveries, of which M. M. Boule gives an interesting account. One important result of his work was the establishment of the Institute at Monaco, where the treasures recovered from the caves find a suitable home, and where the study of them can be conducted.

Our Astronomical Column.

D'ARREST'S COMET. — This interesting periodic comet is due at perihelion in two months, and its detection in July may be hoped for, as it is well placed in the evening sky. Mr. F. R. Cripps has calculated the perturbations by Jupiter and gives the following elements and ephemeris (for midnight) in B.A.A. Journal for May:—

$$T = 1923 \text{ Sept. } 14{\cdot}12 \text{ G.M.T.}$$

$$\left.\begin{array}{l} \omega = 174^\circ\ 7'\ 15'' \\ \Omega = 143\ \ 32\ \ 18 \\ i = 18\ \ 3\ \ 47 \end{array}\right\} 1925{\cdot}0 \qquad \begin{array}{l} e = 0{\cdot}6169 \\ \log a = 0{\cdot}5478 \\ \log q = 0{\cdot}1311 \end{array}$$

	R. A.	N. Decl.	log r	log Δ
July 8.	16h 26·0m	12° 19′	0·193	9·856
,, 12.	16 25·2	11 6		
,, 16.	16 25·2	9 42	0·181	9·847
,, 20.	16 26·1	8 8		
,, 24.	16 28·1	6 24	0·170	9·841

The comet is nearest to the earth at the end of July and brightest in mid-August. The moon will cause difficulty in the latter part of July. The positions given above lie in the southern part of Hercules, and are nearly due south at the end of twilight.

There is no further confirmation of the announcement of the discovery of a comet by Abbot at Athens.

THE COMING OF THE PERSEIDS.—Mr. W. F. Denning writes: "Early meteors from the great August shower are occasionally visible at the beginning of July. They should be carefully observed, as it is desirable to ascertain the opening date of the display. A few meteors, if observed at two stations, might satisfactorily settle the question, though, at its first oncoming, the shower is but slightly manifested. This year there will be no moonlight to interfere with the maximum on about August 11 or 12, and with clear weather the event should be witnessed under good conditions. There is no reason for expecting that the ensuing return will be one of very rich character, but the Perseids form an annual spectacle of meteoric activity not equalled by any other system. A maximum of special intensity was witnessed on the morning of August 12, 1921, when the hourly number of meteors visible to an observer was 250. There is evidence to show that the shower presents itself most richly at intervals of 11·75 years, but more observations are required. Its duration continues over the two summer months of July and August.

"The Perseid shower will be supplemented by other radiants, the following being among the more prominent ones visible at or from about the middle of July and, in certain cases, for some time afterwards:—

16° +31°	47° +44°	303° − 10°	334° +73°
22 +21	270 +47	303 +24	335 +58
25 +43	292 +53	312 +62	339 − 12
42 +22	281 +44	315 +48	343 +12

There are certainly more than 100 different systems in play, but the great majority of them are feeble and apparently the relics of nearly exhausted streams which possibly formed rich displays in ancient times."

PERTURBATIONS OF THE MINOR PLANETS.—Prof. A. O. Leuschner has published a useful report on this subject as a Bulletin of the Research Council of the National Academy of Sciences, Washington. It deals with twenty-three interesting planets, including the four bright ones, Eros, Andromache, and the six Trojan planets. Tables are given of all orbits published, with a statement of the method by which they were derived.

It is obvious that the vast host of minor planets can only be observed efficiently if there is a methodical division of labour. Arrangements for this had been made before the War, which threw them into confusion, and it is welcome news that Prof. Leuschner's Bureau is again making arrangements for this purpose. At present planets that are better known are frequently observed to an unnecessary extent, while others are neglected. Marseilles Observatory has published numerous orbits and ephemerides of late years, but it has not been in touch with all the countries where observations were being made. One point emphasised in the report is the importance of giving clear information in all published orbits of the materials that were used in obtaining them, and the perturbations that were applied. Several cases are quoted in which this information is lacking.

Research Items.

AN EGYPTIAN STATUE OF MENKAURA IN LONDON.—In *Ancient Egypt*, 1923, part i., Prof. Flinders Petrie describes a remarkable figure in white alabaster, acquired some time ago for University College, London. It shows a further development of the great Khofra statue. There the king's head is shielded by the falcon's wings which are spread out behind the head-dress; here the king is himself the falcon god, entirely human in front view, entirely bird-like at the back. The lower part is incomplete, but the figure was probably seated. The resemblance to the *bourgeois* figure of Menkaura is obvious at first sight; and the development of the protecting falcon would accord with this representing the successor of Khofra. It can scarcely be questioned that it came from one of the two temples of Menkaura.

EXCAVATIONS IN UPPER SIND, INDIA.—A dispatch from the Bombay correspondent of the *Times*, published in the issue of June 25, summarises a report of excavations in Upper Sind carried out by Mr. R. D. Banerji, of the Indian Archaeological Survey, on the ruins of an ancient city now known as Mohenjidaro or Mohenjodhari, six miles from Dokri on the North-Western Railway. The highest mound in these ruins, which cover more than two hundred acres, was selected for excavation. It proved to be a Buddhist shrine on an artificial platform situated on an island in the old bed of the Indus. This platform was protected from the effects of high floods by retaining walls some 40-50 feet high. Two more mounds excavated produced remains of shrines dating from the second century A.D. during the reign of the great Kushan Emperor Vasudeva I., A.D. 158–177. A stratum below the shrine contained what were apparently the remains of an older shrine which had been burnt, possibly by Scythian invaders. There are two most interesting features in these investigations. The first is the discovery of a number of coins representing the earliest copper currency of North-Western India, and differing from any discovered hitherto in India in being dye-struck and not punch-marked. These coins also afford the oldest representation of the Fire-Altar of the ancient Persian religion on Asiatic coins, and furnish evidence that this religion and Buddhism flourished side by side. The second point of particular interest is the discovery in one group of coins of inscriptions in unknown characters, as yet undeciphered, which it is maintained are hieroglyphs or ideograms differing from Egyptian hieroglyphs. This is claimed to be the only recorded discovery of a new type of hieroglyph in Asia; but Sir J. Marshall, Director-General of Archæology in India, has since pointed out that these pictographs are similar in character to those from Harappa in the Punjab.

DISCOVERY OF A MIDDEN AND FIRE-HEARTH AT CHARK, NEAR GOSPORT.—In the June issue of *Man*, Lieut.-Colonel J. H. Cooke describes the result of excavations on Chark Common, about one mile from the shores of Spithead. They included a midden and camp fireplaces which were coeval. The midden is unique of its kind, though it is not as large as some of the great shell-heaps on the Continent, but it is the only example of a midden in Britain in which the contents are unmixed with relics of later cultures. Its principal features are the character of the deposits in which it is embedded, the many species of shells it contains, the well-marked types of implements found in it and around the adjacent fire-hearths, and the total absence of any fragments of pottery or metal. It is attributed to the Robenhausen period of the Stone Age, which immediately preceded the Bronze Age.

FOSSIL CRABS FROM HAITI.—Some Brachyuran Crustacea from the Pleistocene and Miocene deposits of Haiti form the subject of a short paper by Miss Mary J. Rathbun (Proc. U.S. Nat. Mus., vol. lxiii. art. 9). One genus, Mithrax, which is widely distributed throughout the West Indies, had not before been found fossil, but is now recorded from the Pleistocene.

MESOZOIC INSECTS OF QUEENSLAND.—Fossil remains of insects are not usually found associated in great abundance at any one spot, so that the discovery of a six-inch seam full of such remains, and that from so low a geological horizon as the Trias, is a noteworthy occurrence. The layer in question was disclosed at Denmark Hill, Ipswich, some few miles west of Brisbane, Queensland, and the description of its insect contents has been undertaken by Dr. R. J. Tillyard and Mr. B. Dunstan. The first part, just issued, is by Mr. Dunstan (Queensland Geol. Surv. Publication, No. 273), and deals with introductory matter and the Coleoptera of the deposit. After describing the section from both the physical-geographical and the geological aspect, the author is tempted to speculate on the cause of the wholesale destruction of insects here manifest. From a study of the phenomena occurring at the hot springs at Einasleigh, Northern Queensland, where the edges of the pools are lined with myriads of wings and elytra, from which the soft parts have evidently been removed by the hot bubbling water, while insect fragments float about and then disappear down the stream, Mr. Dunstan infers that similar conditions governed the formation of the Triassic deposit. The major portion of the paper is devoted to full and careful descriptions of the fifty-eight species, belonging to twenty genera, the bulk of which are of course new, referable to some eight families. The Hydrophilidæ are the most numerous. One could have wished, however, that the seven plates had been executed in a style more consonant with the rest of the work.

A NEW GRASS.—In the *Kew Bulletin*, No. 5 of 1923, D. K. Hughes describes and figures an interesting grass, *Streptolophus sagittifolius* Hughes, which has been grown at Kew from fruits received from Mr. J. Gossweiler, director of the Botanic Garden, Angola. Conspicuous features of the new genus are the sagittate leaf blades, lifted away from the leaf sheaths upon slender petioles which are set at a sharp angle to the main stem, and the flowering panicles, which owe their characteristic appearance to the fact that the branchlets are reduced to slightly flattened bristles which are fused at the base into clusters.

EARTHQUAKES AND PHEASANTS.—Pheasants, it has long been known, are peculiarly sensitive to the effects of slight tremors, and in many earthquake countries they are supposed to give notice of a coming shock. Prof. Sekiya's attempt, nearly forty years ago, to study the behaviour of pheasants before and during earthquakes was unsuccessful, probably because the birds were not under natural conditions. Recently, Prof. Omori (Bull. Imp. Earthq. Inves. Com. of Japan, vol. 11, 1923, pp. 1-5) has been able to observe those living in a neighbouring park, usually within a distance of a hundred yards, and

during the quiet hours of the night. In three years he recorded 22 cases of the disturbance of pheasants. On seven occasions the birds crowed before the tremor was felt, on five at the same time, and on five afterwards. In four cases they crowed while no tremor was felt, though slight movements were recorded by the seismographs; and in only one case did an earthquake occur without the accompaniment of pheasant-crowing. Thus, in half the cases observed, the movement was noticed by pheasants more readily than by a trained observer under good conditions.

NORTH SEA FISHERIES IN 1920–22.—There was something unusual in the physical conditions of the North Sea in 1920–22. A much greater influx of Atlantic water occurred, and the pelagic fauna showed marked deviations from its normal character. The pelagic tunicate, Salpa, appeared in great numbers, and there were swarms of medusæ in regions where they had not usually been seen in quantity. The herring fishery of 1921 was very poor, both as regards the catches made and the quality of the fish. The latter were ill-nourished, and this may be regarded as an indirect effect of the changed physical conditions. Several papers that have appeared recently provide data for a treatment of this remarkable hydrographic occurrence. *Rapports et Procès-Verbaux*, vol. xxix., published in May by the International Council for Fishery Investigations, gives the first report of a committee formed to investigate the Atlantic slope W. and S.W. from the British Isles, and hydrographic and planktonic results for the year 1921 are recorded. *Publications de Circonstance*, Nos. 78, 79, and 80, also published by the Council (in April), contain papers by A. C. Hardy, J. N. Carruthers, and J. R. Lumby, dealing with the plankton, the non-tidal movements of North Sea water, and the salinity and temperature of the southern North Sea and English Channel during 1921. The results are interesting and of importance for a consideration of the causes of the unusual conditions of the North Sea mentioned above. That inadequate food-supply does not completely explain the failure of the herring fishery of 1921 is apparent from results obtained by Mr. B. Storrow (Report of the Dove Marine Laboratory, Cullercoats, Northumberland, for 1922). There was an actual shortage of fish having three winter rings on their scales; this result was obtained from a great number of careful measurements made at Cullercoats. Therefore, whatever happened to make the fishery a failure happened about 1917 as well as in 1921. The failure characterised the North Sea fishery but not that of the Firth of Clyde, and there the 1917 year class of fish was well represented.

CONSTITUTION OF DOLOMITE.—Dolomite has always been regarded by mineralogists as a definite compound, $CaCO_3,MgCO_3$, the reason for this conclusion being apparently the very constant composition of different specimens of the mineral from various parts of the world. The suggestion has recently been made by Spangenberg that the mineral is a solid solution of calcite and magnesite, the limits of miscibility being placed between the proportions $CaCO_3,2MgCO_3$ and $2CaCO_3,MgCO_3$. The substances prepared by him, however, have not the properties of dolomite. The matter has recently been investigated by Mr. A. E. Mitchell, at the suggestion of Prof. Donnan, and the results of some preliminary experiments are given in the May issue of the Journal of the Chemical Society. The dissociation pressure curves of calcite, magnesite, and dolomite have been determined from 700° to 1200°. In the case of calcite it is shown that the equation of Nernst is in good agreement with the results, the more complicated equation of Johnson being not only unnecessary but inaccurate. The curve for dolomite lies about half way between those of calcite and magnesite. Some measurements of the specific heats were made, in order to apply the Nernst equation, and an attempt to measure the heat of formation of dolomite gave the small value of 4·52 kg. cal. per mol. It is concluded that the dissociation of dolomite occurs according to the equation $CaCO_3,MgCO_3 = CaO,MgO + 2CO_2$. The experiments have not, however, been carried far enough to enable a decision to be made as to whether dolomite is a compound or a solid solution.

MOISTURE IN FRESHLY FELLED TIMBER.—In the Notes of the Royal Botanic Garden, Edinburgh, for January 1923, Prof. W. G. Craib has a third paper upon the "Regional Spread of Moisture in the Wood of Trees." As described in the earlier papers, specially selected trees are carefully felled and sections of timber taken for investigation, moisture determinations being separately carried out for blocks at different depths right across the section; this process is repeated at different levels and the results expressed graphically. This interesting line of research not only provides data of great practical interest to the forester, but also contributes to our knowledge of the ascent of sap in trees. Prof. Craib has previously shown that in winter there appears to be considerable storage of sap in the heart-wood of *Acer Pseudoplatanus*, the sap moving outwards later until it is mainly in the outer ring of young wood as the transpiration current becomes active in the summer. The present paper demonstrates a somewhat similar but slower change of sap distribution in the wood of the holly, while in resinous conifers no storage of sap in the heart-wood takes place, probably because the resin hinders radial migration of the sap. In the non-resinous yew tree there is again a storage of sap in the heart-wood. A very interesting plate shows the distribution of sap in a tree of *Populus trichocarpa*, felled on a windy day. In the sapwood on the side towards the wind there is the usual high percentage of moisture, but on the side away from the wind it has fallen very low. Prof. Craib's further papers will be awaited with interest, and there will be general congratulations from his colleagues that this paper seems to show him well on the way to a full renewal of the scientific activities so severely interfered with by his accident at the time that the British Association met in Edinburgh.

EWING'S NEW FERROMAGNETIC MODEL.—In our issue for March 9, 1922, p. 321, we gave an account of the new model of an atom of a ferromagnetic material proposed by Sir Alfred Ewing as an improvement on that brought forward by him in 1890. A portion only of the atom was taken as capable of alignment with the external field, and the controlling force on this part was considered to be due in the main to the fixed portion of the atom. In the February issue of the Science Reports of the University of Sendai, Profs. Honda and Okubo examine the new theory, and show that it is not in agreement with the discontinuous changes of magnetic properties which are found in steels during heating and cooling between 700° and 730° C., nor with those found in pure iron at 910° and 1410° C. respectively. They conclude that the quantitative extensions of the older theory made by them in 1916 and 1917 reproduce the hysteresis loop and the effects of temperature on magnetisation much more accurately than does the new theory.

The Pasteur Centenary Celebrations.

THE national celebrations which took place throughout France on May 24 - June 1 in honour of Louis Pasteur are unique in history, for never before has such a splendid tribute been paid to the memory of a man of science.

The invitations to attend the celebrations were issued jointly by the rector and council of the University of Paris and the rector and council of the University of Strasbourg. The celebrations began on May 24 in Paris with an evening reception tendered by the President of the Republic at the Palace of the Élysée, where a large and distinguished company consisting of diplomatic and scientific representatives from practically all parts of the world were assembled.

On the morning of May 25 Dr. Roux and his colleagues at the Institut Pasteur held a reception, after which the visitors defiled before the tomb of Pasteur, which was decked with floral tributes. Among these, there being many, may be mentioned the wreaths sent by the British Government and the Royal Society, the latter resting at the foot of the monument. Afterwards bronze commemorative medals were distributed among the guests, who had signed their names in a volume which will afford a valuable record of the occasion. Driving homeward along the Boulevard Pasteur, the vehicles conveying the guests halted for a short time in the Place Pasteur before the beflagged monument of Pasteur. In the afternoon the British delegates were summoned by invitations from the University of Paris and Association France-Grande-Bretagne to the "Salle des Autorités" at the Sorbonne, where a tablet commemorating the meeting of Lister and Pasteur was unveiled and the British Ambassador made an appropriate speech. Immediately thereafter followed the ceremonial gathering in the Grand Amphitheatre of the Sorbonne, about 2700 persons being assembled, in the presence of M. Alexandre Millerand, President of the Republic (Chairman), M. Paul Appell, rector of the Paris Academy and president of the council of the University of Paris, Government and academic representatives and others, the picture afforded being most impressive and recalling that painted by Rixens in commemoration of Pasteur's Jubilee in 1892, fine colour effects being afforded by the many academic robes and uniforms. The ceremony began with the singing of the Marseillaise by a large choir of girls to the accompaniment of the band of the Garde Républicaine, the whole audience standing at attention. M. Paul Appell, M. Léon Bérard (Minister of Education and Fine Arts) delivered speeches and were followed by the Papal Nuncio, who conveyed the Pope's blessing on the occasion. As Government delegates, Prof. W. H. Welch spoke on behalf of the United States and Sir Charles Sherrington on behalf of the British Empire; delegates from other countries followed, most of them reading speeches in a French that was difficult to follow. Finally M. Strauss, Minister of Hygiene, delivered an impassioned speech after the foreign delegates had severally presented congratulatory addresses on behalf of various universities and learned bodies, these being handed over unread with no semblance of order. Addresses were presented from the Universities of Oxford, Cambridge, Edinburgh and Liverpool, the Royal Colleges of Physicians and Surgeons of London and Edinburgh, and numerous other bodies.

On May 26 were issued postage stamps (values 10, 30, and 50 centimes) bearing the portrait of Pasteur. A reception was held at the École Normale by M. Gustave Lanson, the director, and the guests were shown the "Cabinet Pasteur" with its interesting mementoes of Pasteur's sojourn and activities at that institution. M. Lanson read out a hitherto unpublished letter of Pasteur's addressed to the French Ministry appealing for financial aid in the prosecution of his researches. This letter revealed the personality of Pasteur in a remarkable manner, his clearness of thought and marvellous prescience being strikingly exhibited; the whole audience was thrilled and felt that M. Lanson's opening words, that he was "about to let Pasteur himself speak to the audience," were indeed justified. It is to be hoped that the letter will soon be published. The company next walked to No. 10 rue des Feuilleantines close-by, to witness the unveiling of a tablet upon the house where Pasteur lived as a student, and, finally, in the evening, a reception was given at the Hôtel de Ville by the Municipality of Paris. Here, as at the Élysée, there were representations by artists of the Comédie Française, and Opéra, etc., the recitation of two of Pasteur's speeches by M. Léon Bernard, of the Comédie, invoking much enthusiasm among the hearers. The speeches were those delivered by Pasteur (*a*) at Dôle in 1883, when a tablet was affixed to the house in which he was born, and (*b*) at the Sorbonne in 1892, on the occasion of his jubilee. An eloquent passage from the latter speech was frequently quoted by orators in the days that followed, and it may well be cited here from a printed copy which was thoughtfully distributed to the guests at the centenary celebration:

"Jeunes gens, jeunes gens, confiez-vous à ces méthodes sûres, puissantes, dont nous ne connaissons encore que les premiers secrets. Et tous, quelle que soit votre carrière, ne vous laissez pas atteindre par le scepticisme dénigrant et stérile; ne vous laissez pas décourager par les tristesses de certaines heures qui passent sur une nation. Vivez dans la paix sereine des laboratoires et des bibliothèques. Dites-vous d'abord: Qu'ai-je fait pour mon instruction? Puis, à mesure que vous avancerez: Qu'ai-je fait pour mon pays? jusqu'au moment où vous aurez peut-être cet immense bonheur de penser que vous avez contribué en quelque chose au progrès et au bien de l'humanité. Mais, que les efforts soient plus ou moins favorisés par la vie, il faut, quand on approche du grand but, être en droit de dire: J'ai fait ce que j'ai pu."

On Sunday, May 27, the Lycée Pasteur was inaugurated in the morning. In the afternoon l'Accueil Franco-Britannique and Dr. and Mme. Tuffier received the British delegates in the charming home of the latter, which, we may mention incidentally, contains a fine collection of pictures. In the evening there were gala representations at the Opéra and Théâtre Français in honour of the foreign delegates. Throughout France, ladies and schoolgirls collected money for the scientific laboratories of the country, some ten differently designed badges, mostly bearing the effigy of Pasteur, being pinned with the tricolor to persons who helped by contributions. All the badges were inscribed on the back with the words: "Journée Pasteur, mai 1923. Au profit des Laboratoires," and a quotation from Pasteur reading: "Sans laboratoires les savants sont des soldats sans armes."

On May 28 the guests were conveyed to the Palace of Versailles, where a banquet was held in the "Gallerie des Batailles," some 900 persons participating under the presidency of M. Reibel, Minister of the Liberated Regions. The latter, in his speech, cited with special emphasis Pasteur's advice to men of science: "Luttons donc dans le champ pacifique de la science pour la prééminence de nos patries respec-

tives. Luttons, car la lutte c'est l'effort, la lutte c'est la vie, quand la lutte a le progrès pour but," adding that it was surely necessary that Pasteur's pronouncement should be repeated "in this Palace with its many significant associations." M. Reibel's speech was followed by those of diplomatic representatives which could not be heard by many because they were delivered across the centre of the very long gallery.

On May 29 some of the guests attended a morning presentation of the cinematograph film entitled "Pasteur" designed to popularise his work. In the afternoon the Institut de France held a garden party at Chantilly, the castle with its art treasures being thrown open for inspection.

Many left Paris on May 30 to attend the concluding ceremonies at Strasbourg, where in the evening a reception was held in the Palais du Rhin.

On May 31 a monument of Pasteur was inaugurated in front of the University of Strasbourg in the presence of the President of the Republic accompanied by M. Poincaré (Prime Minister), M. Strauss (Minister of Hygiene), M. Valery-Radot and others, academic dress being worn by University representatives, a few of whom presented addresses to the University which they delivered into the President's hands. Orations were delivered by M. Charléty (rector of the University), M. Haller (president of the Academy of Sciences), Prof. Bordet (Pasteur Institute, Brussels), and finally M. Millerand spoke with the eloquence of a practised orator in a voice that carried far, his speech being remarkably good. There followed a banquet at noon attended by some thousand persons at the Palais des Fêtes under the presidency of MM. Millerand and Poincaré,. speeches that were more or less audible being delivered by the Mayor of Strasbourg, M. Alapetite (Commissioner General of the Republic), M. Strauss, and others. Following upon the banquet the company assembled at the Palais du Rhin, the ex-Emperor's former palace, to witness the procession of Alsatian Societies before the President; it was a stirring sight, which deeply moved all beholders, to see the representatives from all parts of Alsace and Lorraine, lads and maidens dressed in the characteristic costumes of their districts stepping along briskly hand in hand to the music of numerous bands that accompanied them, while a deeper note was struck as veterans of the War and of the war of 1870 defiled past, all saluting the President of the Republic. There followed the opening ceremonies at the Pasteur Museum and the International Exhibition of Hygiene and an evening reception at the Hôtel de Ville given by the Mayor of Strasbourg. Speeches were made in connexion with these ceremonies, those delivered by Prof. Borrel (Commissary General of the Exhibition) and M. Poincaré being the most notable. The scene at the Hôtel de Ville was remarkable when, from the balcony, M. Millerand addressed the populace assembled in the square and twenty thousand people with upturned faces sang the Marseillaise to the accompaniment of massed bands; it was a sight which none who witnessed it can forget.

The Comité du Centenaire de Pasteur was responsible for all arrangements and, except in minor matters, did their work admirably. The programme was rather overfilled and no lists were available to aid the participants in discovering the names of those who attended the celebrations. A reduction of 50 per cent. was allowed on the cost of tickets from the frontier to Paris, while free first-class return tickets were issued between Paris and Strasbourg to those who had been invited. During two days of the festivities in Paris motor omnibuses were to be found at seven "points de concentration" chosen with regard to the hotels at which delegates resided, thereby affording a very convenient way of transporting them to the various places where ceremonies took place, gentlemen from the Pasteur Institute and others serving as guides to the different parties. Special trains and motor transportation were, moreover, provided for the excursions to Versailles and Chantilly.

Owing to the short time that was at the disposal of the organisers, the Pasteur Museum and the Exhibition at Strasbourg were scarcely ready for inspection, the majority of the exhibits still remaining in their packing cases, this being indeed unfortunate. It is therefore inexpedient to attempt a description of the few objects that could be seen.

Those who attended the celebrations brought away mementoes of the occasion apart from the medal which they received at the Institut Pasteur. Of printed matter may be mentioned the "Souvenir des Fêtes Nationales de la Commémoration du Centenaire de la Naissance de Pasteur, célébrés à Paris, en Franche-Comté et à Strasbourg du 24 au 31 mai, 1923" (Paris: Imprimerie Nationale, 1923). This includes a chronology of Pasteur's chief discoveries (1847–1885), a facsimile of his birth certificate, three portraits of Pasteur at different ages, pictures of his birthplace, homes, and grave, striking citations from his writings, and a facsimile autograph and signature reading: "La grandeur des actions humaines se mesure à l'inspiration qui les fait naître. L. Pasteur, 27 mars 1887." The tasteful menu at the Versailles banquet and the programmes at the gala performances on May 27 bore an excellent profile portrait of Pasteur in flat relief, stamped on silvered paper, reproduced after the well-known plaque by O. Roty. The programmes distributed at Dr. Tuffier's reception and at the Hôtel de Ville bore the finely reproduced profile head of Pasteur executed by R. Lalique. At a private dinner given to some of the delegates, M. Calmette distributed to his guests some finely wrought silver medals bearing Pasteur's head modelled by G. Prudhomme and bearing the dates 1822–1922. It should be mentioned, to avoid confusion, that the national celebration was somewhat belated. In point of date, the true centenary had been previously celebrated in December 1922 at the Institut Pasteur, but these celebrations were, however, more of a domestic character.

During the festivities in Paris, the President of the Republic with a small party left for Franche-Comté, where, on May 26, he visited the house in which Pasteur was born at Dôle, attended a ceremony before Pasteur's monument there and participated at a soirée at Lons-sur-Sonier. On May 27 the presidential party visited the parental house of Pasteur at Arbois and attended ceremonies at Salins and Besançon, university functions at Besançon following on May 28 and 29, *i.e.* prior to the advent of the party in Strasbourg.

It may be mentioned incidentally that the Société de Biologie of Paris celebrated the seventy-fifth anniversary of its foundation on May 26-28, it being arranged that its meetings should clash as little as possible with those relating to the Pasteur centenary. Nevertheless, the present writer unfortunately found it impossible to attend both functions because time for rest was required between the events that constituted the very full programme.

Those who participated in the celebrations above described in a somewhat inadequate manner will have brought away, as did the writer, a delightful recollection of having revived friendships and established firmly new ties across the water.

GEORGE H. F. NUTTALL.

Cambridge Meeting of the International Union for Pure and Applied Chemistry.

THE International Union for Pure and Applied Chemistry met at Cambridge on Sunday, June 17, under the presidency of Sir W. J. Pope, and carried out the programme previously outlined in these columns (June 16, p. 825). The countries which have now joined the Union are the following—The Argentine, Australia, Belgium, Canada, Czechoslovakia, Denmark, France, Great Britain, Greece, Holland, Italy, Japan, Luxemburg, Norway, Peru, Poland, Portugal, Roumania, Spain, Switzerland, the United States of America, Uruguay, and Yougoslavia; over one hundred delegates representing the chemical interests of these countries were in attendance at Cambridge. A feature of the meeting was the presentation of several comprehensive reports on subjects which at the moment present special chemical interest; these were printed and distributed beforehand, and at the meeting brief summaries were presented by their authors, after which general discussions took place.

The report on "The Study of Soap Solutions and its Bearings upon Colloid Chemistry," presented by Prof. J. W. McBain, included a statement of the chief conclusions arrived at by its author in his extended studies of the properties of salts of the higher fatty acids. About one-half of the electrical conductivity of a soap solution is due to a negative carrier, which does not exhibit osmotic activity and is therefore colloidal; this is the ionic micelle, and consists of highly charged and solvated ionic particles. Accompanying the ionic micelle is the undissociated colloidal electrolyte, which consists of electrically neutral micelli. Interesting contributions to the discussion were made by Prof. H. E. Armstrong and Prof. W. D. Bancroft. Dr. E. K. Rideal presented a report on "Recent Developments in Contact Catalysis," in which the conception of Hardy and Langmuir, that adsorption of reactants occurs in monomolecular and orientated films, is shown capable of application to the reactions at the surface of charcoal, studied by Van Kruyt, and at the surface of the enzyme, oxidase, present in liver tissue, as studied by Hopkins.

The report contributed by Prof. J. F. Thorpe and Dr. C. K. Ingold consisted in a summary of the recent work of the authors on "Some New Aspects of Tautomerism." It is claimed that the original definition of the term "tautomerism" should be broadened, in accordance with modern investigation, and that the term should apply to all reversible isomeric change; a reasoned classification of the various types of tautomeric change which have been more carefully studied during recent years is then given. The report by Prof. F. G. Hopkins, on "Chemical Mechanisms involved in the Oxidations which occur in the Living Body," describes the success which has attended the attempts to elucidate the nature of the oxidation processes involved in living tissues by a simple chemical mechanism. In the resulting discussion, Prof. C. Moureu drew a parallel between the course of these apparently complex reactions and the catalytic oxidation of aldehydes which he has himself studied. Mr. W. Barlow showed and described a number of solid models which he has devised for the interpretation, in accordance with the valency volume law, of the results of the X-ray analysis of crystalline materials by the Laue and Bragg method; incidentally he demonstrated an hitherto unknown mode of partitioning space into identical polyhedra.

A large proportion of the time of the meeting was devoted to the work of the numerous committees which are engaged in the attempt to systematise practice throughout the world in connexion with nomenclature, abbreviations, standard methods, tables of constants, and the like.

It was decided that the Union will hold its meeting next year in Copenhagen, on the invitation of the chemical representatives of Denmark. At the concluding ceremony honorary degrees of the University of Cambridge were conferred on a number of distinguished visitors whose names were announced in the preliminary statement on the meeting (NATURE, June 16, p. 825).

Tercentenary of the Oxford Botanic Garden.

THROUGHOUT the three hundred years of its existence, the Oxford Botanic Garden can never have looked more radiant than it did on Saturday, June 23, when it welcomed the distinguished company which met to celebrate the tercentenary of its foundation. Sheltered by high and stately walls from the incessant north-east winds which in spring play havoc in more exposed gardens, it gave the impression of serene beauty, the more impressive because of the simplicity of the lines on which it has been laid out.

Those, however, who know the rigours of the Oxford climate will ascribe the luxuriance of growth of the plants in the garden rather to skill in cultivation than to good fortune with respect of site. For although the walls which surround the garden do, indeed, give shelter, the soil is none too kindly and the Thames water is too near the surface to make cultivation a light or easy task. It was, therefore, no less a tribute to their own perspicacity than to Mr. Baker, the superintendent of the gardens, that more than one speaker referred in terms of admiration to the skill in cultivation which the gardens displayed.

The Chancellor of the University, Lord Curzon, who presided at the tercentenary celebrations, spoke on gardens with the simple sincerity which proves his title to be ranked among the goodly company of true gardeners, and nothing in his speech gave more pleasure to the company which were met together under the trees of the garden than his reminiscences of the happy hours which as undergraduate and fellow he had passed in the Oxford Botanic Garden. For surely this old garden has for three centuries irradiated a happy influence on successive generations whose feet have walked therein and whose eyes have been refreshed by its scenes of peaceful beauty.

Sir David Prain, who followed the Chancellor, traced in a masterly way the history of the Garden from the time of its foundation, by the beneficence of Henry Lord Danvers, on St. James's Day (July 25), 1622. He reminded his hearers that it was in this Garden that the first greenhouses erected in England were put up, and that it was there that experiments were first made in methods of heating them. Bobert the elder and the younger, men of great wisdom; Morison, the great professor of botany and a pioneer of systematic botany; Sherard, the founder of the chair which bears his name; Sibthorpe, who deserves the title of a great botanical explorer; and Daubeny, versatile and generous,

are names which will always live, not only in the history of the Garden but also in that of botany. In more recent times, Bayley Balfour and Sydney Vines have maintained the great traditions of the Garden so that, in despite of difficult times which have occurred in the past and may recur in the future, the permanence and usefulness of the Garden are assured.

The chairman of the curators, Sir Herbert Warren, whose knowledge of the Garden extends over fifty years, in the course of a delightful speech in which he referred to the love which the Garden has inspired in the minds of Oxford men, omitted to mention the great and beneficent part which he himself has played in steering the Garden through the recent difficult years when costs have been so high and the financial resources of the University have been so strained. In helping the Garden to meet the financial difficulties inherent in these times, the University has shown wisdom and understanding that, it may be hoped, will touch the imagination of a generous benefactor and make the Garden secure for all time, not only as a place of botanical study, and as a repository of herbaria of historic and present importance, but also as a quiet sanctuary wherein men who love plants may study and admire them.

Prof. Seward, who in the absence of Lord Ullswater spoke on the subject of gardens as aids to botanical teaching and research, congratulated the University on the fact that gardens and laboratories, library and herbarium, were all assembled in one site. He referred to the generosity of Mr. Reginald Cory and other benefactors in aiding the Cambridge Botanical Garden to maintain itself, and expressed the belief that the value of the work done at Oxford and the need for assistance required only to be known to ensure the supplementing of existing resources by private benefaction.

After the formal ceremony the visitors, who numbered some 500, inspected the gardens and laboratories, admiring particularly the famous tank houses wherein the blue water-lilies (*Nymphæa zanzibarensis*, *N. gigantea*, and *N. stellata*) thrive with amazing floriferousness in company with many other Nymphæas, *Nelumbium speciosum*, the white rose-tipped Egyptian Bean of Pythagoras, *Cyperus papyrus*, graceful and historical and the source of the papyrus of antiquity, and a large assemblage of aquatic and marsh plants, all of which are of interest and collectively give a memorable impression of luxuriance which few parts of the tropics can rival.

After tea in the gardens the ceremony terminated, the departing guests averring that few among them had realised so clearly as they now did the vital part which botanic gardens play and have played in the social life of civilised communities.

University and Educational Intelligence.

EDINBURGH.—Prof. F. Gowland Hopkins, Cameron prizeman for 1922, delivered two lectures in the University on June 27 and 28 respectively, on the present position of the vitamin question. The Cameron prize, which was founded in 1878, is awarded annually to an investigator who in the course of the five years immediately preceding has made an important addition to practical therapeutics.

SHEFFIELD.—Dr. P. J. Daniell has been appointed to the Town Trust chair of mathematics.

AN Edward K. Dunham lectureship has been established at Harvard University in memory of the late Prof. E. K. Dunham, for many years professor of pathology in the Bellevue and University Medical College of New York City (*Science*, June 15). According to the terms of the gift, which is made by Prof. Dunham's widow, the lectures are to be given annually by eminent investigators and teachers in medical science or one of the contributory basic sciences, and there is no restriction as to the nationality of the lecturer. It is hoped that the foundation may "serve to bind closer the bonds of friendship and understanding between students and investigators in this and foreign countries."

AN outline of President Harding's plan for reorganising the educational activities of the Federal Government was given by the United States Commissioner of Education at the recent annual meeting of the Department of Superintendence of the National Education Association. The plan is a part of a comprehensive scheme, foreshadowed by the President in his first message to Congress and presented to the Senate in February, for a reorganisation of all the executive departments, including the establishment of a department to promote citizenship and general welfare. The educational work now carried on by some thirty separate agencies, belonging to six of the principal departments and several independent establishments, is to be included along with certain other services, the whole costing at present 700 million dollars a year, in a new Department of Education and Welfare comprising education, public health, social service, and veteran relief. The Division of Education, which will be under a permanent assistant secretary, will take over, *inter alia*, in addition to the Bureau of Education and the Board for Vocational Education, the Smithsonian Institution, including the National Museum and Art Gallery, the International Exchange Service, the Bureau of American Ethnology, the Astrophysical Observatory, the National Zoological Park, and the International Catalogue of Scientific Literature, and will create and direct an entirely new bureau for promoting physical education. The scheme is to come before Congress in December.

THE work of the University of London during the year 1922–23, measured by the usual statistical standards, shows a notable expansion. The Principal Officer, while careful to point out that the great mass of the university's continuous achievement is the expression of imponderable forces, directs attention to figures 75-200 per cent. higher than the corresponding figures for 1913–14, and points out that "we have passed well beyond the wash of what was commonly regarded as the abnormal demand for educational facilities that followed the great deliverance of 1918"; the figures are as follows: admissions (8498), candidates for degrees (3191), candidates for matriculation and registration (19,985), and other examinations (7663), and internal students (8881). There has been a noticeable decrease in the percentage of successful to total candidates from 53 in 1913–14 to 32 in 1922–23. The "growth of ignorance" among the younger generation to which Prof. John Burnet directed attention recently in the Romanes lecture is apparently not confined to Scotland. Indicative of the ever-growing specialisation of the subjects of the curricula is the increase in the number of Boards of Studies from 27 with 374 members in 1900 to 42 with 1051 members. That the senate is alive to the dangers incidental to this specialisation and resolved to guard against them is shown by its creation of a Board of Studies in "the principles, history, and method of science," designed to embrace not only the natural and mathematical sciences, but also logic, ethics, history, pedagogy, economics, linguistics, archæology, scholarship, and medicine.

Societies and Academies.

LONDON.

Royal Society, June 28.—V. H. **Blackman**, A. T. **Legg**, and F. A. **Gregory**: The effect of a direct electric current of very low intensity on the rate of growth of the coleoptile of barley. The coleoptile (sheathed plumule or young stem) of barley seedlings is exposed to an electric discharge from a point charged *positively* to about 10,000 volts (crest value) and placed at such a height above the coleoptile that a current of $0 \cdot 5 \times 10^{-10}$ amp. passes through it, the current density being 4×10^{-9} amp. per cm.^{2} Under these conditions the rate of growth is markedly accelerated from the first hour onward, showing in the third hour a percentage increase above that of the control plants of $7 \cdot 53 \pm 1 \cdot 95$. After the cessation of the current a well-marked after-effect, greater than the direct effect, is observed, the enhanced rate of growth steadily continuing and showing a percentage increase of $15 \cdot 68 \pm 2 \cdot 62$ above that of the controls. The after-effect is greater with a short period of discharge of 1 hour than with a longer period of 3 hours. When the point is *negatively* charged the rate of growth is increased during the first hour, but the increase becomes less with time. An after-effect follows, but it is markedly less. The gaseous products of the discharge and the "electric wind" play little or no part in the stimulation of growth observed. The current alone appears to be of importance.—M. S. **Pembrey**, N. W. **MacKeith**, W. R. **Spurrell**, E. C. **Warner**, and H. J. **Westlake**: Observations on the adjustment of the human body to muscular work. In the dyspnœa produced by running there is a disturbance of the acid-base equilibrium of the body; the relief of "second wind" is the result of adjustments effected chiefly by the respiration, circulation, and excretion by the kidneys and skin. The sense of discomfort during dyspnœa is associated with increased pulmonary ventilation, the sense of relief at the onset of second wind with diminished ventilation. Oliguria, or anuria, appears as a constant feature during running, even after taking 560 c.c. of tea as a diuretic. It leads to a temporary retention of acid, which helps the body to get rid of carbon dioxide and obtain oxygen; the water spared is available for excretion by the lungs and skin, and will produce by evaporation greater cooling than it would if it were discharged as urinary water. The suspension of the activity of the kidneys appears to be due to an outflow of constrictor impulses to the renal vessels.—Miss R. M. **Tupper-Carey** and J. H. **Priestley**: The composition of the cell wall at the apical meristem of stem and root. The walls of the apical meristem of stem and root differ in the ease with which cellulose may be detected in them with iodine reagents. Macro- and micro-chemical experiments show that the cellulose in the wall of the root meristem is masked by its combination with other substances, particularly proteins and fatty acids. In the shoot meristem, the cellulose is closely linked with larger quantities of pectin, but less protein and fatty acid are present, especially when the shoot is growing in the light. —L. J. **Harris**: The titration of amino- and carboxyl-groups in amino-acids, polypeptides, etc.—F. A. E. **Crew**: Studies in intersexuality. II. Sex-reversal in the fowl.—W. **Finkler**: Analytical studies on the factors causing the sexual display in the mountain newt (*Triton alpestris*).—G. A. **Schott**: On the scattering of X- and γ-rays by rings of electrons. The effect of damping of the incident radiation. Damping of the usual type, of an amount compatible with the production of moderately sharp lines in the X-ray spectrum, increases slightly the total scattering of short waves, such as the hard γ-rays, although it decreases slightly that of long waves. A single electron ring, such as is postulated in hydrogen and ionised helium on Bohr's theory, is completely unaffected by this type of damping. It seems scarcely possible that damping can diminish the total scattering for any type of atom below the amount required by the simple pulse theory.—P. A. **MacMahon**: On a class of transcendents of which the Bessel functions are a particular case.—L. C. **Martin**: The photometric matching field. Improvement in the visibility of faint contrasts observed with central vision can be obtained by stimulating the peripheral regions of the retina. An increase in precision of the order of 30 per cent. is obtained in photometric matches by surrounding the photometric field with a larger area of approximately equal brightness.—G. P. **Thomson**: Test of a theory of radiation. Experiments with positive rays show that visual and photographic effects can be obtained with trains of waves shorter than those produced in the emission of a quantum of light.—A. Ll. **Hughes** and P. **Lowe**: Intensities in the helium spectrum. The curve showing the intensity of any spectrum line as a function of the energy of impact of the electrons is characteristic of the series to which it belongs. The intensities in the doublet system all decrease rapidly as the energy of impact is increased from 34 volts. The principal series, $1S - mP$, of the singlet system is characterised by a very great increase in intensity as the energy of impact is increased from 34 volts up to about 80 volts, beyond which there is little change. The lines of the diffuse series, $1P - mD$, all show a maximum at about 75 volts. The lines of the sharp series, $1P - mS$, after a small initial rise to 60 volts, decrease slightly.—A. A. **Dee**: The effect of quenching from above the carbide transition temperature upon the magnetism of steel. The magnetism of steel at ordinary temperatures is not materially altered by quenching from above the transition temperature of iron carbide, and therefore the return of the carbide to the ferromagnetic state is not retarded by sudden cooling from above the transition temperature.—T. S. P. **Strangeways** and H. E. H. **Oakley**: The immediate changes observed in tissue cells after exposure to soft X-rays while growing *in vitro*. Exposures for gradually increasing periods, varying from 5 minutes to 2 hours, were used. There is a latent period of about 15 to 20 minutes before the changes produced in the cells by irradiation can be recognised. After 5 minutes irradiation development of new dividing cells is lessened. After exposure of 20 minutes or longer the formation of new dividing cells practically ceases. After exposure of 5 minutes granular changes and fragmentation of the chromosomes occurs in some cells in mitosis at metaphase and anaphase. After exposure of 25 minutes or longer some cells in mitosis show clumping of the chromosomes at metaphase. As the time of exposure increases there is increase in size and alteration in structure of the cytoplasm, nucleus, and nucleolus of some fully formed cells. After an exposure of 60 minutes, affected cells become disorganised, and eventually cytoplasm and nucleus break up and appear to go into solution in the surrounding medium.—W. B. **Hardy** and Ida **Doubleday**: Boundary lubrication: the latent period and mixtures of two lubricants.—C. T. R. **Wilson**: Investigations on X-rays and β-rays by the cloud method. Pt. I.—X-rays. The tracks of the electron ejected from the atom which emits the quantum of radiation and that of the electron ejected from the atom which absorbs the radiation can be identified.

Two classes of β-ray tracks are produced in air by the primary action of X-radiation of wave-length less than about 0·5 Å: (*a*) those of ejected electrons with initial kinetic energy comparable to a quantum of the incident radiation, and (*b*) tracks of very short range. The short-range electrons are ejected nearly along the direction of the primary X-rays. The short-range tracks are probably related to the phenomena which have led to the postulation of a "J"-radiation. Of the ordinary long-range tracks, the majority have a large forward component comparable with the lateral component; about 20 per cent. are ejected almost exactly at right angles to the primary X-ray beam; others have a large backward component. Partial polarisation of the primary beams is indicated by the direction of ejection of a number of the β-particles being in one plane—that containing the direction of the cathode rays in the X-ray tube. β-rays in air exposed to X-rays frequently occur in pairs or groups. The pairs probably consist of one K electron ejected by the direct action of the primary X-rays, and of a second electron ejected by the combined action of primary radiation and of the K-radiation from the atom from which the first electron was ejected. Pt. II.—β-rays. The tracks of fast β-particles are very nearly straight over distances of several centimetres. Near the end of their range the deviations are of three kinds: (*a*) sudden deviations often through large angles up to 180°, the results of a close approach to the nucleus of an atom; (*b*) sudden deviations ranging up to 45°, due to a close approach to an electron which is in consequence ejected to form a branch track generally approximately at right angles to the deflected primary track; (*c*) gradual deviations due to an accumulation of deviations of (*a*) or (*b*) type. The range of the β-ray as measured along the track is approximately proportional to the square of the kinetic energy or to the fourth power of the velocity (Whiddington's law) for ranges from about 0·1 m. to 2 cm.; the range is 1 cm. when the kinetic energy of the particle is about 21,000 volts. The primary ionisation (*i.e.* number of atoms from which electrons are ejected by the direct action of primary β-rays) is about 90 per cm. for a velocity of 10^{10} cm. per sec., and is approximately inversely as the square of the velocity. The total ionisation per cm., including that due to secondary β-particles of range too short to form visible branch tracks, is about three or four times as large as the primary. In portions of some of the tracks not only is the primary ionisation recorded, but also the ions which each of these electrons has itself produced may be counted.—C. V. **Raman** and K. R. **Ramanathan**: The molecular scattering of light in carbon-dioxide at high pressures.—W. A. **Davis** and J. V. **Eyre**: The discontinuity of the hydration process.—G. M. B. **Dobson**: A flicker type of photoelectric photometer giving high precision.—H. D. **Smyth**: The ionisation of nitrogen by electron impact.—G. M. B. **Dobson**: Measurements of the sun's ultra-violet radiation and its absorption in the earth's atmosphere.—H. **Hartridge** and F. J. W. **Roughton**: A method of measuring the velocity of very rapid chemical reactions.—W. T. **Astbury**: The crystalline structure of anhydrous racemic acid.—E. **Ponder**: The measurement of percentage hæmolysis. I.—H. M. **Fox**: Lunar periodicity in reproduction.—Marjory **Stephenson** and Margaret D. **Whetham**: Studies in the fat metabolism of the Timothy grass bacillus. II. Carbon balance sheet and respiratory quotient.—H. R. **Hewer**: Studies in amphibian colour changes. II.—R. H. **Burne**: Some peculiarities of the blood-vascular system of the Porbeagle shark (*Lamna Cornubica*).—A. E. **Boycott** and C. **Diver**: The inheritance of sinistrality in *Limnæa peregra*.

EDINBURGH.

Royal Society, May 21.—Prof. F. O. Bower, president, in the chair.—R. **Kidston** and W. H. **Lang**: (1) On *Palæopitys Milleri* (McNab). The original specimen of this stem with secondary thickening was described by Hugh Miller, and later named by McNab. A second specimen, discovered by the Geological Survey of Scotland, includes the primary central region, 1·5 mm. in diameter, surrounded by a zone of secondary xylem about 1 cm. thick. The secondary wood consists of tracheides and medullary rays. The tracheides are remarkable in having multiseriate, porose pitting on both radial and tangential walls. The primary central axis appears to have consisted of tracheides without admixture of parenchyma. There is evidence of strands of protoxylem, consisting of narrow spiral tracheides, close to the periphery of the primary xylem, just within the secondary wood. In the absence of any traces going to lateral appendages it is impossible to determine the affinities of this complex stem. It might have belonged to some gymnospermous plant, but it is equally possible that it was the stem of some archaic pteridophyte of the Middle Old Red Sandstone Period. (2) Notes on fossil plants from the Old Red Sandstone of Scotland. I. *Hicklingia Edwardi*, K. and L. Under this name a unique specimen of a Middle Old Red Sandstone plant is described and figured. It was discovered many years ago by the late Mr. G. Edward, and is preserved in the University of Manchester Museum. It occurs as an incrustation, and suggests comparison with a plant of the nature of the Rhyniaceæ spread out on a slab of Caithness flagstone. Diverging from an obscure basal region is a tuft of linear axes, without leaves, but branched dichotomously and laterally. There are indications of the presence of a slender central strand. Many of the stems terminate in oval carbonised bodies that are evidently large sporangia. The plant is compared with Rhynia and Hornea, which are known as petrifactions from the Rhynie Chert.—W. T. **Gordon**: The genus Pitys. Fossil trees belonging to this genus have been known since 1831, and it was in describing these specimens that thin sections of fossil wood were first used. A recent discovery at Gullane has disclosed twigs and stems of this type, in some cases still clothed in bark and in two specimens with leaves attached. These leaves resemble petioles in their structure, and are undoubtedly phyllodes. *Pitys dayi* affords evidence of the phyllode theory of leaf formation in gymnosperms. Pitys shows marked resemblance to Araucaria as regards the structure of the wood (recognised long ago) and the leaf-traces and leaves.

PARIS.

Academy of Sciences, June 11.—M. Albin Haller in the chair.—Edouard **Imbeaux**: The artesian basins of Australia. A map of Australia is reproduced showing the artesian basins known at the present time, taken from the report of the interstate conference on artesian water held at Adelaide in 1921.—M. Jean Perrin was elected a member of the section of general physics in succession to the late M. E. Bouty.—Paul **Montel**: Algebraic relations of class one or zero.—René **Garnier**: Uniform functions of two independent variables defined by the inversion of an algebraic system to total differentials of the fourth order.—Charles N. **Moore**: The summability of Cesàro for double Fourier's series.—Louis **Bachelier**: The general problem of discontinuous statistics.—

Stanislas **Millot**: Simplified solutions of problems of Laplace on the probability of causes.—B. **Hostinský**: The equilibrium of electricity on a cylindrical surface. —Th. De **Donder**: Synthesis of the gravific.—Adolphe **Lepape**: The radioactivity of the springs from some watering-places in the Pyrenees (Bagnères-de-Luchon, Vernet, les Escaldes, Thuès) and of the Central Plateau (la Bourboule, Royat, Saint-Nectaire, Sail-les-Bains). Determinations of the radium emanation in gases and waters from forty-four springs. Search for the thorium emanation gave mostly negative results, a few springs only showing a trace.—Albert **Nodon**: The relations between the radioactivity of radium and the activity of solar radiations. —F. **Bourion** and E. **Rouyer**: The determination of double salts in solution by the boiling-point method. A discussion of the validity of the rule of mixtures as applied to the boiling-point elevations of solutions of two electrolytes.—Jacques **Bardet**: The arc spectrum of celtium. The material used contained as impurities only zirconium and a trace of lead, and was obtained from zircons from Brazilian monazite sand. Wave-lengths of the lines in the region between 2300 and 3500 Å. are given.—Paul **Pascal**: Researches on the constitution of insoluble alkaline metaphosphates. The insoluble alkaline metaphosphates are not monometaphosphates, but furnish a remarkable example of colloids prepared at a temperature of about 850° C. The normal formula, MPO_3, should be restricted to the salts obtained starting with ethyl hexametaphosphate.—S. **Glixelli**: The influence of neutral salts on the silica gels. The acid properties of colloidal silica are increased by the addition of salts of the alkalis: the effects observed can be explained by assuming that the (OH) ions are adsorbed by the particles of silica.—A. **Mailhe**: The catalytic decomposition of the anilides. An account of the decomposition of acetanilide at 400° C. in the presence of nickel and of copper.—R. **Fosse** and A. **Hieulle**: Xanthyl derivatives of allophanic acid, thiosinamine and of allantoine.—Conrad **Kilian**: The folds of the "Tassilian enclosure" of the central Saharan massif of Ahaggar.—A. **Boit**: The rôle of the superficial folds in the structure of the formation at Morvan.—Ch. **Maurain** and Mme. de **Madinhac**: The secular variation of the intensity of the terrestrial magnetic field at Paris. Bauer has suggested the use of a local magnetic constant $G=\sqrt{H^2+(Z/2)^2}$, where H and Z are the horizontal and vertical components of the magnetic field at any point. From an examination of the records for Coimbra, Pola, Paris, Kew, Greenwich, and De Bilt, it is shown that G reached a maximum in 1902. The value of G increases with the latitude of the stations.—J. **Giral** and F. A. **Gila**: The use of sodium chloride as a standard in the estimation of the halogens in sea water. The salts present in sea water have no appreciable influence on the quantitative determination of chlorine.—J. J. **Thomasset**: Relations between the dentine and dental enamel in a fossil fish (Sargodon).—P. **Bugnon**: The homologies of cotyledonous leaves.—L. **Blaringhem**: Heredity in mosaic of the doubling of the flowers in *Cardamine pratensis*.—A. **Guillaumin**: The vacuum as a means of prolonging the germinating faculty of seeds. Seeds of radish, wheat, and lettuce, after preservation in a vacuum in the dark for 12 years, showed unimpaired powers of germination.—A. de **Puymaly**: The adaptation to aerial life of a green alga (*Chlamydomonas fungicola*).—Marc. **Bridel**: Biochemical study of the composition of *Monotropa Hypopitys*: a new glucoside, monotropeine. The new glucoside was isolated in a pure crystalline condition, 2 gm. being obtained from 5200 gm. of material. It is hydrolysed by emulsion giving a blue precipitate. Monotropeine is not identical with aucubine.—Charles **Henry**: A new test for sense of touch.—Jules **Courtier**: Experiments on a new test for the sense of touch. Results of the application of the method described in the preceding communication to nineteen subjects.—P. **Masson** and Louis **Berger**: A new mode of internal secretion.—Louis **Desliens**: The measurement of arterial pressure by the bleeding method. A very exact hæmodynamometric method and present application. The artery is punctured by a hollow needle communicating with a delicate pressure-gauge of the aneroid type. The instrument before use is filled with a saline solution to prevent coagulation.—J. **Lopez-Lomba**: Changes of weight of the organs of the guinea-pig during C-avitaminosis.—F. **Franchette**: The pneumo-anæsthesiograph. An account of an instrument designed to evaluate and record the amplitude and frequency of the respiratory movements during anæsthesia.—Emile F. **Terroine** and H. **Barthélemy**: The composition of the eggs in the course of ovogenesis in the brown frog (*Rana fusca*).—M. **Caille** and E. **Viel**: The detection of small quantities of antimony and bismuth in biological liquids. An application of the antipyrine-potassium iodide reagent described in an earlier communication.—M. **Lemoigne**: The production of β-oxybutyric acid by certain bacteria of the *B. subtilis* group.—Charles **Pérez**: The casting of the shell of decapod crustaceans carrying parasites (Epicaridæ).—Boris **Ephrussi**: The sexuality of *Clava squamata*.—C. **Levaditi** and T. **Nicolau**: Tissue immunity in neurotrope ectodermosis.—Emile **Gautrelet**: Monomethylorthophospho-salicylic acid.

Supplement to NATURE 29

No. 2801 JULY 7, 1923

The Structure of the Atom.[1]

By Prof. N. Bohr.

The General Picture of the Atom.

THE present state of atomic theory is characterised by the fact that we not only believe the existence of atoms to be proved beyond a doubt, but also we even believe that we have an intimate knowledge of the constituents of the individual atoms. I cannot on this occasion give a survey of the scientific developments that have led to this result; I will only recall the discovery of the electron towards the close of the last century, which furnished the direct verification and led to a conclusive formulation of the conception of the atomic nature of electricity which had evolved since the discovery by Faraday of the fundamental laws of electrolysis and Berzelius's electrochemical theory, and had its greatest triumph in the electrolytic dissociation theory of Arrhenius. This discovery of the electron and elucidation of its properties was the result of the work of a large number of investigators, among whom Lenard and J. J. Thomson may be particularly mentioned. The latter especially has made very important contributions to our subject by his ingenious attempts to develop ideas about atomic constitution on the basis of the electron theory. The present state of our knowledge of the elements of atomic structure was reached, however, by the discovery of the atomic nucleus, which we owe to Rutherford, whose work on the radioactive substances discovered towards the close of the last century has much enriched physical and chemical science.

According to our present conceptions, an atom of an element is built up of a nucleus that has a positive electrical charge and is the seat of by far the greatest part of the atomic mass, together with a number of electrons, all having the same negative charge and mass, which move at distances from the nucleus that are very great compared to the dimensions of the nucleus or of the electrons themselves. In this picture we at once see a striking resemblance to a planetary system, such as we have in our own solar system. Just as the simplicity of the laws that govern the motions of the solar system is intimately connected with the circumstance that the dimensions of the moving bodies are small in relation to the orbits, so the corresponding relations in atomic structure provide us with an explanation of an essential feature of natural phenomena in so far as these depend on the properties of the elements. It makes clear at once that these properties can be divided into two sharply distinguished classes.

To the first class belong most of the ordinary physical and chemical properties of substances, such as their state of aggregation, colour, and chemical reactivity. These properties depend on the motion of the electron system and the way in which this motion changes under the influence of different external actions. On account of the large mass of the nucleus relative to that of the electrons and its smallness in comparison to the electron orbits, the electronic motion will depend only to a very small extent on the nuclear mass, and will be determined to a close approximation solely by the total electrical charge of the nucleus. Especially the inner structure of the nucleus and the way in which the charges and masses are distributed among its separate particles will have a vanishingly small influence on the motion of the electron system surrounding the nucleus. On the other hand, the structure of the nucleus will be responsible for the second class of properties that are shown in the radioactivity of substances. In the radioactive processes we meet with an explosion of the nucleus, whereby positive or negative particles, the so-called α- and β-particles, are expelled with very great velocities.

Our conceptions of atomic structure afford us, therefore, an immediate explanation of the complete lack of interdependence between the two classes of properties, which is most strikingly shown in the existence of substances which have to an extraordinarily close approximation the same ordinary physical and chemical properties, even though the atomic weights are not the same, and the radioactive properties are completely different. Such substances, of the existence of which the first evidence was found in the work of Soddy and other investigators on the chemical properties of the radioactive elements, are called isotopes, with reference to the classification of the elements according to ordinary physical and chemical properties. It is

[1] Lecture delivered at Stockholm, December 11, 1922, on the occasion of the receipt of the Nobel prize in physics for the year 1922. English translation by Dr. Frank C. Hoyt.

not necessary for me to state here how it has been shown in recent years that isotopes are found not only among the radioactive elements, but also among ordinary stable elements; in fact, a large number of the latter that were previously supposed simple have been shown by Aston's well-known investigations to consist of a mixture of isotopes with different atomic weights.

The question of the inner structure of the nucleus is still but little understood, although a method of attack is afforded by Rutherford's experiments on the disintegration of atomic nuclei by bombardment with α-particles. Indeed, these experiments may be said to open up a new epoch in natural philosophy in that for the first time the artificial transformation of one element into another has been accomplished. In what follows, however, we shall confine ourselves to a consideration of the ordinary physical and chemical properties of the elements and the attempts which have been made to explain them on the basis of the concepts just outlined.

It is well known that the elements can be arranged as regards their ordinary physical and chemical properties in a *natural system* which displays most suggestively the peculiar relationships between the different elements. It was recognised for the first time by Mendeléeff and Lothar Meyer that when the elements are arranged in an order which is practically that of their atomic weights, their chemical and physical properties show a pronounced periodicity. A diagrammatic representation of this so-called periodic table is given in Fig. 1, where, however, the elements are not arranged in the ordinary way but in a somewhat modified form of a table first given by Julius Thomsen, who has also made important contributions to science in this domain. In the figure the elements are denoted by their usual chemical symbols, and the different vertical columns indicate the so-called periods. The elements in successive columns which possess homologous chemical and physical properties are connected with lines. The meaning of the square brackets around certain series of elements in the later periods, the properties of which exhibit typical deviations from the simple periodicity in the first periods, will be discussed later.

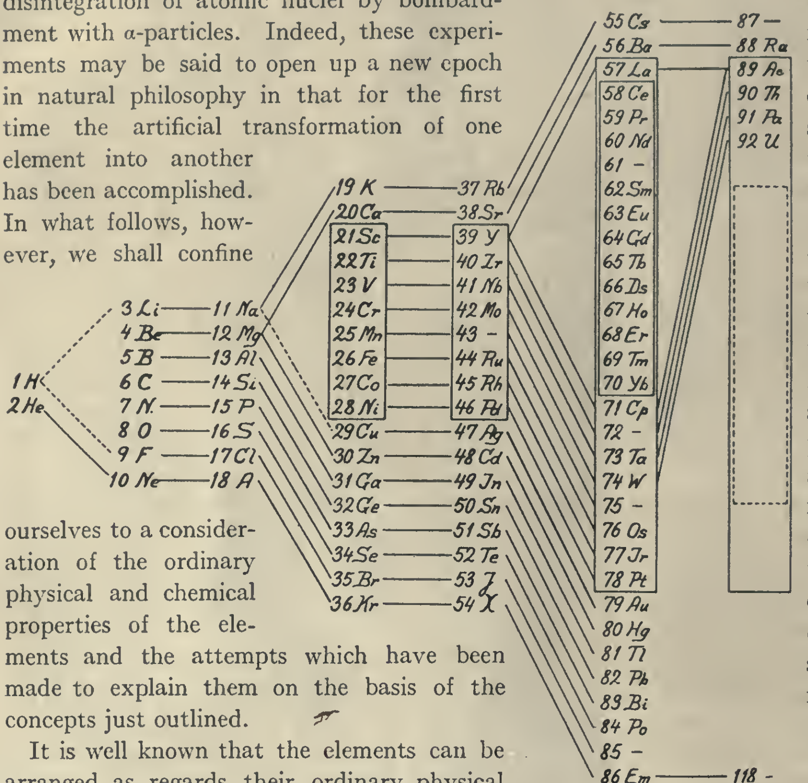

Fig. 1.

In the development of the theory of atomic structure the characteristic features of the natural system have found a surprisingly simple interpretation. Thus we are led to assume that the ordinal number of an element in the periodic table, the so-called atomic number, is just equal to the number of electrons which move about the nucleus in the neutral atom. In an imperfect form, this law was first stated by Van den Broek; it was, however, foreshadowed by J. J. Thomson's investigations of the number of electrons in the atom, as well as by Rutherford's measurements of the charge on the atomic nucleus. As we shall see, convincing support for this law has since been obtained in various ways, especially by Moseley's famous investigations of the X-ray spectra of the elements. We may perhaps also point out, how the simple connexion between atomic number and nuclear charge offers an explanation of the laws governing the changes in chemical properties of the elements after expulsion of α- or β-particles, which found a simple formulation in the so-called radioactive displacement law.

Atomic Stability and Electrodynamic Theory.

As soon as we try to trace a more intimate connexion between the properties of the elements and atomic structure, we encounter profound difficulties, in that essential differences between an atom and a planetary system show themselves here in spite of the analogy we have mentioned.

The motions of the bodies in a planetary system, even though they obey the general law of gravitation, will not be completely determined by this law alone, but will depend largely on the previous history of the system. Thus the length of the year is not determined by the masses of the sun and the earth alone, but depends also on the conditions that existed during the formation of the solar system, of which we have very little knowledge. Should a sufficiently large foreign body some day traverse our solar system, we might among other effects expect that from that

day the length of the year would be different from its present value.

It is quite otherwise in the case of atoms. The definite and unchangeable properties of the elements demand that the state of an atom cannot undergo permanent changes due to external actions. As soon as the atom is left to itself again, its constituent particles must arrange their motions in a manner which is completely determined by the electric charges and masses of the particles. We have the most convincing evidence of this in spectra, that is, in the properties of the radiation emitted from substances in certain circumstances, which can be studied with such great precision. It is well known that the wave-lengths of the spectral lines of a substance, which can in many cases be measured with an accuracy of more than one part in a million, are, in the same external circumstances, always exactly the same within the limit of error of the measurements, and quite independent of the previous treatment of this substance. It is just to this circumstance that we owe the great importance of spectral analysis, which has been such an invaluable aid to the chemist in the search for new elements, and has also shown us that even on the most distant bodies of the universe there occur elements with exactly the same properties as on the earth.

On the basis of our picture of the constitution of the atom it is thus impossible, so long as we restrict ourselves to the ordinary mechanical laws, to account for the characteristic atomic stability which is required for an explanation of the properties of the elements.

The situation is by no means improved if we also take into consideration the well-known electrodynamic laws which Maxwell succeeded in formulating on the basis of the great discoveries of Oersted and Faraday in the first half of the last century. Maxwell's theory has not only shown itself able to account for the already known electric and magnetic phenomena in all their details, but has also celebrated its greatest triumph in the prediction of the electromagnetic waves which were discovered by Hertz, and are now so extensively used in wireless telegraphy.

For a time it seemed as though this theory would also be able to furnish a basis for an explanation of the details of the properties of the elements, after it had been developed, chiefly by Lorentz and Larmor, into a form consistent with the atomistic conception of electricity. I need only remind you of the great interest that was aroused when Lorentz, shortly after the discovery by Zeeman of the characteristic changes that spectral lines undergo when the emitting substance is brought into a magnetic field, could give a natural and simple explanation of the main features of the phenomenon. Lorentz assumed that the radiation which we observe in a spectral line is sent out from an electron executing simple harmonic vibrations about a position of equilibrium in precisely the same manner as the electromagnetic waves in radio-telegraphy are sent out by the electric oscillations in the antennæ. He also pointed out how the alteration observed by Zeeman in the spectral lines corresponded exactly to the alteration in the motion of the vibrating electron which one would expect to be produced by the magnetic field.

It was, however, impossible on this basis to give a closer explanation of the spectra of the elements, or even of the general type of the laws holding with great exactness for the wave-lengths of lines in these spectra, which had been established by Balmer, Rydberg, and Ritz. After we obtained details as to the constitution of the atom, this difficulty became still more manifest; in fact, so long as we confine ourselves to the classical electrodynamic theory we cannot even understand why we obtain spectra consisting of sharp lines at all. This theory can even be said to be incompatible with the assumption of the existence of atoms possessing the structure we have described, in that the motions of the electrons would claim a continuous radiation of energy from the atom, which would cease only when the electrons had fallen into the nucleus.

The Origin of the Quantum Theory.

It has, however, been possible to avoid the various difficulties of the electrodynamic theory by introducing concepts borrowed from the so-called quantum theory, which marks a complete departure from the ideas that have hitherto been used for the explanation of natural phenomena. This theory was originated by Planck, in the year 1900, in his investigations on the law of heat radiation, which, because of its independence of the individual properties of substances, lent itself peculiarly well to a test of the applicability of the laws of classical physics to atomic processes.

Planck considered the equilibrium of radiation between a number of systems with the same properties as those on which Lorentz had based his theory of the Zeeman effect, but he could now show not only that classical physics could not account for the phenomena of heat radiation, but also that a complete agreement with the experimental law could be obtained if—in pronounced contradiction to classical theory—it were assumed that the energy of the vibrating electrons could not change continuously, but only in such a way that the energy of the system always remained equal to a whole number of so-called energy-quanta. The magnitude of this quantum was found

to be proportional to the frequency of oscillation of the particle, which, in accordance with classical concepts, was supposed to be also the frequency of the emitted radiation. The proportionality factor had to be regarded as a new universal constant, since termed Planck's constant, similar to the velocity of light and the charge and mass of the electron.

Planck's surprising result stood at first completely isolated in natural science, but with Einstein's significant contributions to this subject a few years after, a great variety of applications was found. In the first place, Einstein pointed out that the condition limiting the amount of vibrational energy of the particles could be tested by investigation of the specific heat of crystalline bodies, since in the case of these we have to do with similar vibrations, not of a single electron, but of whole atoms about positions of equilibrium in the crystal lattice. Einstein was able to show that the experiment confirmed Planck's theory, and through the work of later investigators this agreement has proved quite complete. Furthermore, Einstein emphasised another consequence of Planck's results, namely, that radiant energy could only be emitted or absorbed by the oscillating particle in so-called "quanta of radiation," the magnitude of each of which was equal to Planck's constant multiplied by the frequency.

In his attempts to give an interpretation of this result, Einstein was led to the formulation of the so-called "hypothesis of light-quanta," according to which the radiant energy, in contradiction to Maxwell's electromagnetic theory of light, would not be propagated as electromagnetic waves, but rather as concrete light atoms, each with an energy equal to that of a quantum of radiation. This concept led Einstein to his well-known theory of the photo-electric effect. This phenomenon, which had been entirely unexplainable on the classical theory, was thereby placed in a quite different light, and the predictions of Einstein's theory have received such exact experimental confirmation in recent years, that perhaps the most exact determination of Planck's constant is afforded by measurements on the photo-electric effect. In spite of its heuristic value, however, the hypothesis of light-quanta, which is quite irreconcilable with so-called interference phenomena, is not able to throw light on the nature of radiation. I need only recall that these interference phenomena constitute our only means of investigating the properties of radiation and therefore of assigning any closer meaning to the frequency which in Einstein's theory fixes the magnitude of the light-quantum.

In the following years many efforts were made to apply the concepts of the quantum theory to the question of atomic structure, and the principal emphasis was sometimes placed on one and sometimes on the other of the consequences deduced by Einstein from Planck's result. As the best known of the attempts in this direction, from which, however, no definite results were obtained, I may mention the work of Stark, Sommerfeld, Hasenöhrl, Haas, and Nicholson.

From this period also dates an investigation by Bjerrum on infra-red absorption bands, which, although it had no direct bearing on atomic structure, proved significant for the development of the quantum theory. He directed attention to the fact that the rotation of the molecules in a gas might be investigated by means of the changes in certain absorption lines with temperature. At the same time he emphasised the fact that the effect should not consist of a continuous widening of the lines such as might be expected from classical theory, which imposed no restrictions on the molecular rotations, but in accordance with the quantum theory he predicted that the lines should be split up into a number of components, corresponding to a sequence of distinct possibilities of rotation. This prediction was confirmed a few years later by Eva von Bahr, and the phenomenon may still be regarded as one of the most striking evidences of the reality of the quantum theory, even though from our present point of view the original explanation has undergone a modification in essential details.

The Quantum Theory of Atomic Constitution.

The question of further development of the quantum theory was in the meantime placed in a new light by Rutherford's discovery of the atomic nucleus (1911). As we have already seen, this discovery made it quite clear that by classical conceptions alone it was quite impossible to understand the most essential properties of atoms. One was therefore led to seek for a formulation of the principles of the quantum theory that could immediately account for the stability in atomic structure and the properties of the radiation sent out from atoms, of which the observed properties of substances bear witness. Such a formulation was proposed (1913) by the present lecturer in the form of two postulates, which may be stated as follows:

1. Among the conceivably possible states of motion in an atomic system there exist a number of so-called *stationary states* which, in spite of the fact that the motion of the particles in these states obeys the laws of classical mechanics to a considerable extent, possess a peculiar, mechanically unexplainable stability, of such a sort that every permanent change in the motion of the system must consist in a complete transition from one stationary state to another.

2. While in contradiction to the classical electromagnetic theory no radiation takes place from the atom in the stationary states themselves, a process of transition between two stationary states can be accompanied by the emission of electromagnetic radiation, which will have the same properties as that which would be sent out according to the classical theory from an electrified particle executing an harmonic vibration with constant frequency. This frequency ν has, however, no simple relation to the motion of the particles of the atom, but is given by the relation

$$h\nu = E' - E'',$$

where h is Planck's constant, and E' and E'' are the values of the energy of the atom in the two stationary states that form the initial and final state of the radiation process. Conversely, irradiation of the atom with electromagnetic waves of this frequency can lead to an absorption process, whereby the atom is transformed back from the latter stationary state to the former.

While the first postulate has in view the general stability of the atom, the second postulate has chiefly in view the existence of spectra with sharp lines. Furthermore, the quantum theory condition entering in the last postulate affords a starting point for the interpretation of the laws of series spectra. The most general of these laws, the combination principle enunciated by Ritz, states that the frequency ν for each of the lines in the spectrum of an element can be represented by the formula

$$\nu = T'' - T',$$

where T'' and T' are two so-called "spectral terms" belonging to a manifold of such terms characteristic of the substance in question.

According to our postulates, this law finds an immediate interpretation in the assumption that the spectrum is emitted by transitions between a number of stationary states in which the numerical value of the energy of the atom is equal to the value of the spectral term multiplied by Planck's constant. This explanation of the combination principle is seen to differ fundamentally from the usual ideas of electrodynamics, as soon as we consider that there is no simple relation between the motion of the atom and the radiation sent out. The departure of our considerations from the ordinary ideas of natural philosophy becomes particularly evident, however, when we observe that the occurrence of two spectral lines, corresponding to combinations of the same spectral term with two other different terms, implies that the nature of the radiation sent out from the atom is not determined only by the motion of the atom at the beginning of the radiation process, but also depends on the state to which the atom is transferred by the process.

At first glance one might, therefore, think that it would scarcely be possible to bring our formal explanation of the combination principle into direct relation with our views regarding the constitution of the atom, which, indeed, are based on experimental evidence interpreted on classical mechanics and electrodynamics. A closer investigation, however, should make it clear that a definite relation may be obtained between the spectra of the elements and the structure of their atoms on the basis of the postulates.

The Hydrogen Spectrum.

The simplest spectrum we know is that of hydrogen. The frequencies of its lines may be represented with great accuracy by means of Balmer's formula:

$$\nu = K\left(\frac{1}{n''^2} - \frac{1}{n'^2}\right),$$

where K is a constant and n' and n'' are two integers. In the spectrum we accordingly meet a single series of spectral terms of the form K/n^2, which decrease regularly with increasing term number n. In accordance with the postulates, we shall therefore assume that each of the hydrogen lines is emitted by a transition between two states belonging to a series of stationary states of the hydrogen atom in which the numerical value of the atom's energy is equal to hK/n^2.

Following our picture of atomic structure, a hydrogen atom consists of a positive nucleus and an electron which—so far as ordinary mechanical conceptions are applicable—will with great approximation describe a periodic elliptical orbit with the nucleus at one focus. The major axis of the orbit is inversely proportional to the work necessary completely to remove the electron from the nucleus, and, in accordance with the above, this work in the stationary states is just equal to hK/n^2. We thus arrive at a manifold of stationary states for which the major axis of the electron orbit takes on a series of discrete values proportional to the squares of the whole numbers. The accompanying Fig. 2 shows these relations diagrammatically. For the sake of simplicity the electron orbits in the stationary states are represented by circles, although in reality the theory places no restriction on the eccentricity of the orbit, but only determines the length of the major axis. The arrows represent the transition processes that correspond to the red and green hydrogen lines, Hα and Hβ, the frequency of which is given by means of the Balmer formula when we put $n'' = 2$ and $n' = 3$ and 4 respectively. The transition processes are also represented which correspond to the first three lines of the series

of ultra-violet lines found by Lyman in 1914, of which the frequencies are given by the formula when n is put equal to 1, as well as to the first line of the infra-red series discovered some years previously by Paschen, which are given by the formula if n'' is put equal to 3.

This explanation of the origin of the hydrogen spectrum leads us quite naturally to interpret this spectrum as the manifestation of a process whereby the electron is bound to the nucleus. While the largest spectral term with term number 1 corresponds to the final stage in the binding process, the small spectral terms that have larger values of the term number correspond to stationary states which represent the initial states of the binding process, where the

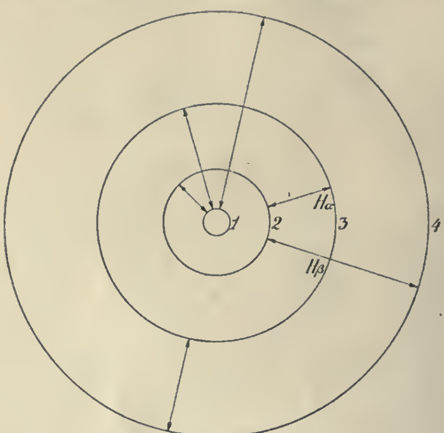

Fig. 2.

electron orbits still have large dimensions, and where the work required to remove an electron from the nucleus is still small. The final stage in the binding process we may designate as the normal state of the atom, and it is distinguished from the other stationary states by the property that, in accordance with the postulates, the state of the atom can only be changed by the addition of energy whereby the electron is transferred to an orbit of larger dimensions corresponding to an earlier stage of the binding process.

The size of the electron orbit in the normal state calculated on the basis of the above interpretation of the spectrum agrees roughly with the value for the dimensions of the atoms of the elements that have been calculated by the kinetic theory of matter from the properties of gases. Since, however, as an immediate consequence of the stability of the stationary states that is claimed by the postulates, we must suppose that the interaction between two atoms during a collision cannot be completely described with the aid of the laws of classical mechanics, such a comparison as this cannot be carried further on the basis of such considerations as those just outlined.

A more intimate connexion between the spectra and the atomic model has been revealed, however, by an investigation of the motion in those stationary states where the term number is large, and where the dimensions of the electron orbit and the frequency of revolution in it vary relatively little when we go from one stationary state to the next following. It was possible to show that the frequency of the radiation sent out during the transition between two stationary states, the difference of the term numbers of which is small in comparison to these numbers themselves, tended to coincide in frequency with one of the harmonic components into which the electron motion could be resolved, and accordingly also with the frequency of one of the wave trains in the radiation which would be emitted according to the laws of ordinary electrodynamics.

The condition that such a coincidence should occur in this region where the stationary states differ but little from one another proves to be that the constant in the Balmer formula can be expressed by means of the relation

$$K = \frac{2\pi^2 e^4 m}{h^3},$$

where e and m are respectively the charge and mass of the electron, while h is Planck's constant. This relation has been shown to hold to within the considerable accuracy with which, especially through the beautiful investigations of Millikan, the quantities e, m, and h are known.

This result shows that there exists a connexion between the hydrogen spectrum and the model for the hydrogen atom which, on the whole, is as close as we might hope considering the departure of the postulates from the classical mechanical and electrodynamic laws. At the same time, it affords some indication of how we may perceive in the quantum theory, in spite of the fundamental character of this departure, a natural generalisation of the fundamental concepts of the classical electrodynamic theory. To this most important question we shall return later, but first we will discuss how the interpretation of the hydrogen spectrum on the basis of the postulates has proved suitable in several ways, for elucidating the relation between the properties of the different elements.

Relationships between the Elements.

The discussion above can be applied immediately to the process whereby an electron is bound to a nucleus with any given charge. The calculations show that, in the stationary state corresponding to a given value of the number n, the size of the orbit will be inversely proportional to the nuclear charge, while the work necessary to remove an electron will be directly proportional to the square of the nuclear charge. The spectrum that is emitted during the binding of an electron by a nucleus with charge N

times that of the hydrogen nucleus can therefore be represented by the formula:

$$\nu = N^2 K\left(\frac{1}{n''^2} - \frac{1}{n'^2}\right).$$

If in this formula we put $N=2$, we get a spectrum which contains a set of lines in the visible region which was observed many years ago in the spectrum of certain stars. Rydberg assigned these lines to hydrogen because of the close analogy with the series of lines represented by the Balmer formula. It was never possible to produce these lines in pure hydrogen, but just before the theory for the hydrogen spectrum was put forward, Fowler succeeded in observing the series in question by sending a strong discharge through a mixture of hydrogen and helium. This investigator also assumed that the lines were hydrogen lines, because there existed no experimental evidence from which it might be inferred that two different substances could show properties resembling each other so much as the spectrum in question and that of hydrogen. After the theory was put forward, it became clear, however, that the observed lines must belong to a spectrum of helium, but that they were not like the ordinary helium spectrum emitted from the neutral atom. They came from an ionised helium atom which consists of a single electron moving about a nucleus with double charge. In this way there was brought to light a new feature of the relationship between the elements, which corresponds exactly with our present ideas of atomic structure, according to which the physical and chemical properties of an element depend in the first instance only on the electric charge of the atomic nucleus.

Soon after this question was settled the existence of a similar general relationship between the properties of the elements was brought to light by Moseley's well-known investigations on the characteristic X-ray spectra of the elements, which was made possible by Laue's discovery of the interference of X-rays in crystals and the investigations of W. H. and W. L. Bragg on this subject. It appeared, in fact, that the X-ray spectra of the different elements possessed a much simpler structure and a much greater mutual resemblance than their optical spectra. In particular, it appeared that the spectra changed from element to element in a manner that corresponded closely to the formula given above for the spectrum emitted during the binding of an electron to a nucleus, provided N was put equal to the atomic number of the element concerned. This formula was even capable of expressing, with an approximation that could not be without significance, the frequencies of the strongest X-ray lines, if small whole numbers were substituted for n' and n''.

This discovery was of great importance in several respects. In the first place, the relationship between the X-ray spectra of different elements proved so simple that it became possible to fix without ambiguity the atomic number for all known substances, and in this way to predict with certainty the atomic number of all such hitherto unknown elements for which there is a place in the natural system. Fig. 3 shows how the square root of the frequency for two characteristic X-ray lines depends on the atomic number. These lines belong to the group of so-called K-lines, which are the most penetrating of the characteristic rays. With very close approximation the points lie on straight lines, and the fact that they do so is conditioned not only by our taking account of known elements, but also by our leaving an open place between molybdenum (42) and ruthenium (44), just as in Mendeléeff's original scheme of the natural system of the elements.

Fig. 3.

Further, the laws of X-ray spectra provide a confirmation of the general theoretical conceptions, both with regard to the constitution of the atom and the ideas that have served as a basis for the interpretation

of spectra. Thus the similarity between X-ray spectra and the spectra emitted during the binding of a single electron to a nucleus may be simply interpreted from the fact that the transitions between stationary states with which we are concerned in X-ray spectra are accompanied by changes in the motion of an electron in the inner part of the atom, where the influence of the attraction of the nucleus is very great compared with the repulsive forces of the other electrons.

The relations between other properties of the elements are of a much more complicated character, which originates in the fact that we have to do with processes concerning the motion of the electrons in the outer part of the atom, where the forces that the electrons exert on one another are of the same order of magnitude as the attraction towards the nucleus, and where, therefore, the details of the interaction of the electrons play an important part. A characteristic example of such a case is afforded by the spatial extension of the atoms of the elements. Lothar Meyer himself directed attention to the characteristic periodic change exhibited by the ratio of the atomic weight to the density, the so-called atomic volume, of the elements in the natural system. An idea of these facts is given by Fig. 4, in which the atomic volume is represented as a function of the atomic number. A greater difference between this and the previous figure could scarcely be imagined. While the X-ray spectra vary uniformly with the atomic number, the atomic volumes show a characteristic periodic change which corresponds exactly to the change in the chemical properties of the elements.

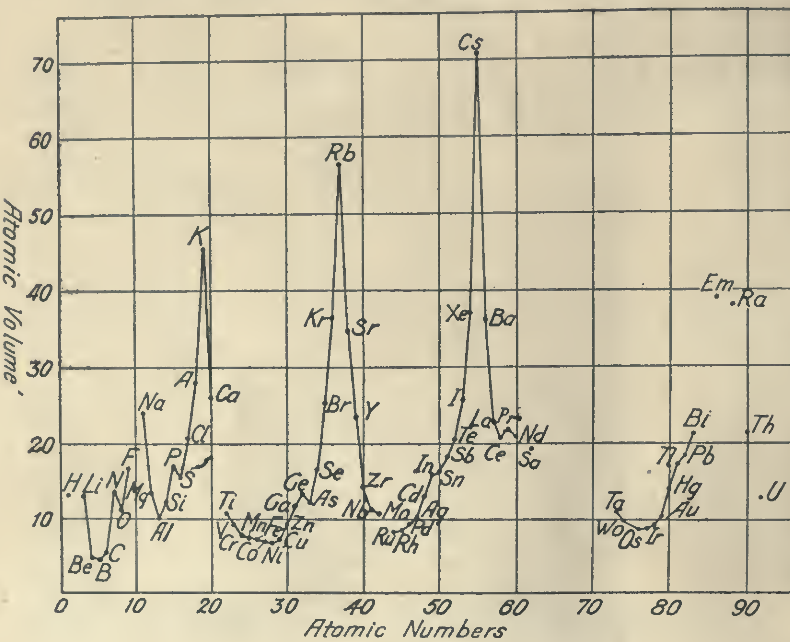

Fig. 4.

Ordinary optical spectra behave in an analogous way. In spite of the dissimilarity between these spectra, Rydberg succeeded in tracing a certain general relationship between the hydrogen spectrum and other spectra. Even though the spectral lines of the elements with higher atomic number appear as combinations of a more complicated manifold of spectral terms which is not so simply co-ordinated with a series of whole numbers, still the spectral terms can be arranged in series each of which shows a strong similarity to the series of terms in the hydrogen spectrum. This similarity appears in the fact that the terms in each series can, as Rydberg pointed out, be very accurately represented by the formula $K/(n+\alpha)^2$, where K is the same constant that occurs in the hydrogen spectrum, often called the Rydberg constant, while n is the term number, and α a constant which is different for the different series.

This relationship with the hydrogen spectrum leads us immediately to regard these spectra as the *last step of a process whereby the neutral atom is built up by the capture and binding of electrons to the nucleus*, one by one. In fact, it is clear that the last electron captured, so long as it is in that stage of the binding process in which its orbit is still large compared to the orbits of the previously bound electrons, will be subjected to a force from the nucleus and these electrons, that differs but little from the force with which the electron in the hydrogen atom is attracted towards the nucleus while it is moving in an orbit of corresponding dimensions.

The spectra so far considered, for which Rydberg's laws hold, are excited by means of electric discharge under ordinary conditions and are often called arc spectra. The elements emit also another type of spectrum, the so-called spark spectra, when they are subjected to an extremely powerful discharge. Hitherto it was impossible to disentangle the spark spectra in the same way as the arc spectra. Shortly after the above view on the origin of arc spectra was brought forward, however, Fowler found (1914) that an empirical expression for the spark spectrum lines could be established which corresponds exactly to Rydberg's laws with the single difference that the constant K is replaced by a constant four times as large. Since, as we have seen, the constant that appears in the spectrum sent out during the binding

of an electron to a helium nucleus is exactly equal to 4 K, it becomes evident that spark spectra are due to the ionised atom, and that their emission corresponds to *the last step but one in the formation of the neutral atom* by the successive capture and binding of electrons.

Absorption and Excitation of Spectral Lines.

The interpretation of the origin of the spectra was also able to explain the characteristic laws that govern absorption spectra. As Kirchhoff and Bunsen had already shown, there is a close relation between the selective absorption of substances for radiation and their emission spectra, and it is on this that the application of spectrum analysis to the heavenly bodies essentially rests. Yet on the basis of the classical electromagnetic theory, it is impossible to understand why substances in the form of vapour show absorption for certain lines in their emission spectrum and not for others.

On the basis of the postulates given above we are, however, led to assume that the absorption of radiation corresponding to a spectral line emitted by a transition from one stationary state of the atom to a state of less energy is brought about by the return of the atom from the last-named state to the first. We thus understand immediately that in ordinary circumstances a gas or vapour can only show selective absorption for spectral lines that are produced by a transition from a state corresponding to an earlier stage in the binding process to the normal state. Only at higher temperatures or under the influence of electric discharges whereby an appreciable number of atoms are being constantly disrupted from the normal state, can we expect absorption for other lines in the emission spectrum in agreement with the experiments.

A most direct confirmation for the general interpretation of spectra on the basis of the postulates has also been obtained by investigations on the excitation of spectral lines and ionisation of atoms by means of impact of free electrons with given velocities. A decided advance in this direction was marked by the well-known investigations of Franck and Hertz (1914). It appeared from their results that by means of electron impacts it was impossible to impart to an atom an arbitrary amount of energy, but only such amounts as corresponded to a transfer of the atom from its normal state to another stationary state of the existence of which the spectra assure us, and the energy of which can be inferred from the magnitude of the spectral term.

Further, striking evidence was afforded of the independence that, according to the postulates, must be attributed to the processes which give rise to the emission of the different spectral lines of an element. Thus it could be shown directly that atoms that were transferred in this manner to a stationary state of greater energy were able to return to the normal state with emission of radiation corresponding to a single spectral line.

Continued investigations on electron impacts, in which a large number of physicists have shared, have also produced a detailed confirmation of the theory concerning the excitation of series spectra. Especially it has been possible to show that for the *ionisation* of an atom by electron impact an amount of energy is necessary that is exactly equal to the work required, according to the theory, to remove the last electron captured from the atom. This work can be determined directly as the product of Planck's constant and the spectral term corresponding to the normal state, which, as mentioned above, is equal to the limiting value of the frequencies of the spectral series connected with selective absorption.

The Quantum Theory of Multiply-Periodic Systems.

While it was thus possible by means of the fundamental postulates of the quantum theory to account directly for certain general features of the properties of the elements, a closer development of the ideas of the quantum theory was necessary in order to account for these properties in further detail. In the course of the last few years a more general theoretical basis has been attained through the development of formal methods that permit the fixation of the stationary states for electron motions of a more general type than those we have hitherto considered. For a simply periodic motion such as we meet in the pure harmonic oscillator, and at least to a first approximation, in the motion of an electron about a positive nucleus, the manifold of stationary states can be simply co-ordinated to a series of whole numbers. For motions of the more general class mentioned above, the so-called *multiply-periodic* motions, however, the stationary states compose a more complex manifold, in which, according to these formal methods, each state is characterised by several whole numbers, the so-called "quantum numbers."

In the development of the theory a large number of physicists have taken part, and the introduction of several quantum numbers can be traced back to the work of Planck himself. But the definite step which gave the impetus to further work was made by Sommerfeld (1915) in his explanation of the fine structure shown by the hydrogen lines when the spectrum is observed with a spectroscope of high resolving power. The occurrence of this fine structure must be ascribed to the circumstance that we have to deal, even in hydrogen, with a motion which is not exactly simply periodic. In fact, as a consequence of the change in the electron's mass with velocity that is claimed by the theory of relativity, the electron orbit will undergo a very slow precession in the orbital plane. The motion will therefore be doubly periodic, and besides a number characterising the term in the Balmer formula, which we shall call the *principal quantum number* because it determines in the main the energy of the atom, the fixation of the stationary

states demands another quantum number which we shall call the *subordinate quantum number*.

A survey of the motion in the stationary states thus fixed is given in the diagram (Fig. 5), which reproduces the relative size and form of the electron orbits. Each orbit is designated by a symbol n_k, where n is the principal quantum number and k the subordinate quantum number. All orbits with the same principal quantum number have, to a first approximation, the same major axis, while orbits with the same value of k have the same parameter, *i.e.* the same value for the shortest chord through the focus. Since the energy values for different states with the same value of n but different values of k differ a little from each other, we get for each hydrogen line corresponding to definite values of n' and n'' in the Balmer formula a number of different transition processes, for which the frequencies of the emitted radiation as calculated by the second postulate are

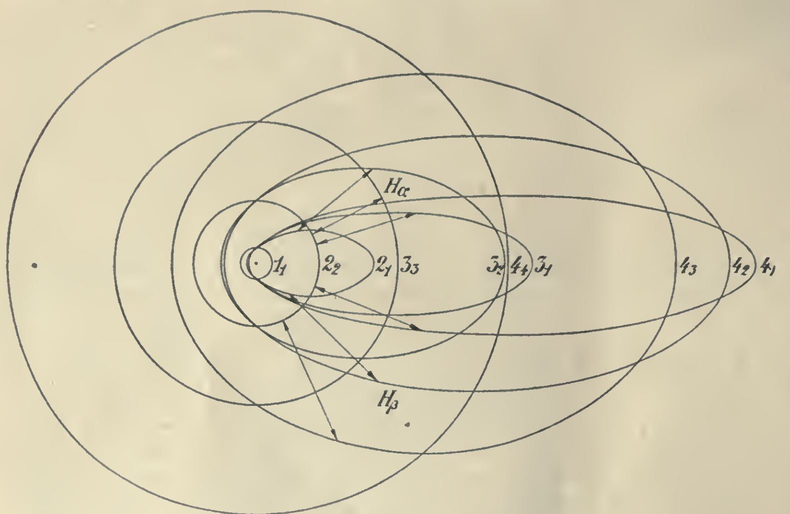

FIG. 5.

not exactly the same. As Sommerfeld was able to show, the components this gives for each hydrogen line agree with the observations on the fine structure of hydrogen lines to within the limits of experimental error. In the figure the arrows designate the processes that give rise to the components of the red and green lines in the hydrogen spectrum, the frequencies of which are obtained by putting $n''=2$ and $n'=3$ or 4 respectively in the Balmer formula.

In considering the figure it must not be forgotten that the description of the orbit is there incomplete, in so much as with the scale used the slow precession does not show at all. In fact, this precession is so slow that even for the orbits that rotate most rapidly the electron performs about 40,000 revolutions before the perihelion has gone round once. Nevertheless, it is this precession alone that is responsible for the multiplicity of the stationary states characterised by the subordinate quantum number. If, for example, the hydrogen atom is subjected to a small disturbing force which perturbs the regular precession, the electron orbit in the stationary states will have a form altogether different from that given in the figure. This implies that the fine structure will change its character completely, but the hydrogen spectrum will continue to consist of lines that are given to a close approximation by the Balmer formula, due to the fact that the approximately periodic character of the motion will be retained. Only when the disturbing forces become so large that even during a single revolution of the electron the orbit is appreciably disturbed, will the spectrum undergo essential changes. The statement often advanced that the introduction of two quantum numbers should be a necessary condition for the explanation of the Balmer formula must therefore be considered as a misconception of the theory.

Sommerfeld's theory has proved itself able to account not only for the fine structure of the hydrogen lines, but also for that of the lines in the helium spark spectrum. Owing to the greater velocity of the electron, the intervals between the components into which a line is split up are here much greater and can be measured with much greater accuracy. The theory was also able to account for certain features in the fine structure of X-ray spectra, where we meet frequency differences that may even reach a value more than a million times as great as those of the frequency differences for the components of the hydrogen lines.

Shortly after this result had been attained, Schwarzschild and Epstein (1916) simultaneously succeeded, by means of similar considerations, in accounting for the characteristic changes that the hydrogen lines undergo in an electric field, which had been discovered by Stark in the year 1914. Next, an explanation of the essential features of the Zeeman effect for the hydrogen lines was worked out at the same time by Sommerfeld and Debye (1917). In this instance the application of the Postulates involved the consequence that only certain orientations of the atom relative to the magnetic field were allowable, and this characteristic consequence of the quantum theory has quite recently received a most direct confirmation in the beautiful researches of Stern and Gerlach on the deflexion of swiftly-moving silver atoms in a non-homogenous magnetic field.

The Correspondence Principle.

While this development of the theory of spectra was based on the working out of formal methods for the fixation of stationary states, the present lecturer succeeded shortly afterwards in throwing light on the theory from a new view-point, by pursuing further the characteristic connexion between the quantum theory and classical electrodynamics already traced out in the hydrogen spectrum. In connexion with the important work of Ehrenfest and Einstein these efforts led to the formulation of the so-called *correspondence principle*, according to which the occurrence of transitions between the stationary states accompanied by emission of radiation is traced back to the harmonic components into which the motion

of the atom may be resolved and which, according to the classical theory, determine the properties of the radiation to which the motion of the particles gives rise.

According to the correspondence principle, it is assumed that every transition process between two stationary states can be co-ordinated with a corresponding harmonic vibration component in such a way that the probability of the occurrence of the transition is dependent on the amplitude of the vibration. The state of polarisation of the radiation emitted during the transition depends on the further characteristics of the vibration, in a manner analogous to that in which on the classical theory the intensity and state of polarisation in the wave system emitted by the atom as a consequence of the presence of this vibration component would be determined respectively by the amplitude and further characteristics of the vibration.

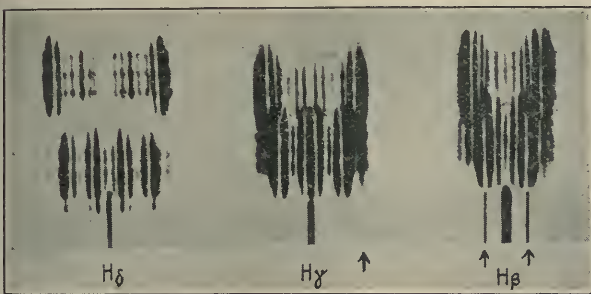

Fig. 6.

With the aid of the correspondence principle it has been possible to confirm and to extend the above-mentioned results. Thus it was possible to develop a complete quantum theory explanation of the Zeeman effect for the hydrogen lines, which, in spite of the essentially different character of the assumptions that underlie the two theories, is very similar throughout to Lorentz's original explanation based on the classical theory. In the case of the Stark effect, where, on the other hand, the classical theory was completely at a loss, the quantum theory explanation could be so extended with the help of the correspondence principle as to account for the polarisation of the different components into which the lines are split, and also for the characteristic intensity distribution exhibited by the components. This last question has been more closely investigated by Kramers, and the accompanying figure will give some impression of how completely it is possible to account for the phenomenon under consideration.

Fig. 6 reproduces one of Stark's well-known photographs of the splitting up of the hydrogen lines. The picture displays very well the varied nature of the phenomenon, and shows in how peculiar a fashion the intensity varies from component to component. The components below are polarised perpendicular to the field, while those above are polarised parallel to the field.

Fig. 7 gives a diagrammatic representation of the experimental and theoretical results for the line Hγ, the frequency of which is given by the Balmer formula with $n''=2$ and $n'=5$. The vertical lines denote the components into which the line is split up, of which the picture on the right gives the components which are polarised parallel to the field and that on the left those that are polarised perpendicular to it. The experimental results are represented in the upper half of the diagram, the distances from the dotted line representing the measured displacements of the components, and the lengths of the lines being proportional to the relative intensity as estimated by Stark from the blackening of the photographic plate. In the lower half is given for comparison a representation of the theoretical results from a drawing in Kramers' paper.

The symbol $(n'_{s'} - n''_{s''})$ attached to the lines gives the transitions between the stationary states of the atom in the electric field by which the components are emitted. Besides the principal quantum integer n, the stationary states are further characterised by a subordinate quantum integer s, which can be negative as well as positive and has a meaning quite different from that of the quantum number k occurring in the relativity theory of the fine structure of the hydrogen lines, which fixed the form of the electron orbit in the undisturbed atom. Under the influence of the electric field both the form of the orbit and its position undergo large changes, but certain properties of the orbit remain unchanged, and the subordinate quantum number s is connected with these. In Fig. 7 the position of the components corresponds to the frequencies calculated for the different transitions, and the lengths of the lines are proportional to the probabilities as calculated on the basis of the correspondence principle, by which also the polarisation of the radiation is determined. It is seen that the theory reproduces completely the main feature of the experimental results, and in the light of the correspondence principle we can say that the Stark effect reflects down to the smallest details the action of the electric field on the orbit of the electron in the hydrogen atom, even though in this case the reflection is so distorted that, in contrast with the case of the Zeeman effect, it would scarcely be possible directly to recognise the motion on the basis of the classical ideas of the origin of electromagnetic radiation.

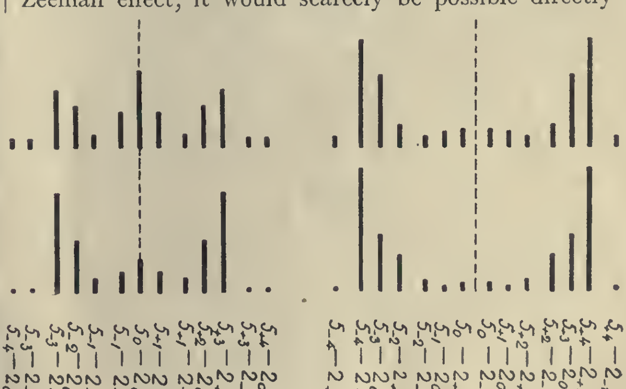

Fig. 7.

Results of interest were also obtained for the spectra of elements of higher atomic number, the explanation of which in the meantime had made important progress through the work of Sommerfeld, who introduced several quantum numbers for the description of the

electron orbits. Indeed, it was possible, with the aid of the correspondence principle, to account completely for the characteristic rules which govern the seemingly capricious occurrence of combination lines, and it is not too much to say that the quantum theory has not only provided a simple interpretation of the combination principle, but has further contributed materially to the clearing up of the mystery that has long rested over the application of this principle.

The same view-points have also proved fruitful in the investigation of the so-called band spectra. These do not originate, as do series spectra, from individual atoms, but from molecules; and the fact that these spectra are so rich in lines is due to the complexity of the motion entailed by the vibrations of the atomic nuclei relative to each other and the rotations of the molecule as a whole. The first to apply the postulates to this problem was Schwarzschild, but the important work of Heurlinger especially has thrown much light on the origin and structure of band spectra. The considerations employed here can be traced back directly to those discussed at the beginning of this lecture in connexion with Bjerrum's theory of the influence of molecular rotation on the infra-red absorption lines of gases. It is true we no longer think that the rotation is reflected in the spectra in the way claimed by classical electrodynamics, but rather that the line components are due to transitions between stationary states which differ as regards rotational motion. That the phenomenon retains its essential features, however, is a typical consequence of the correspondence principle.

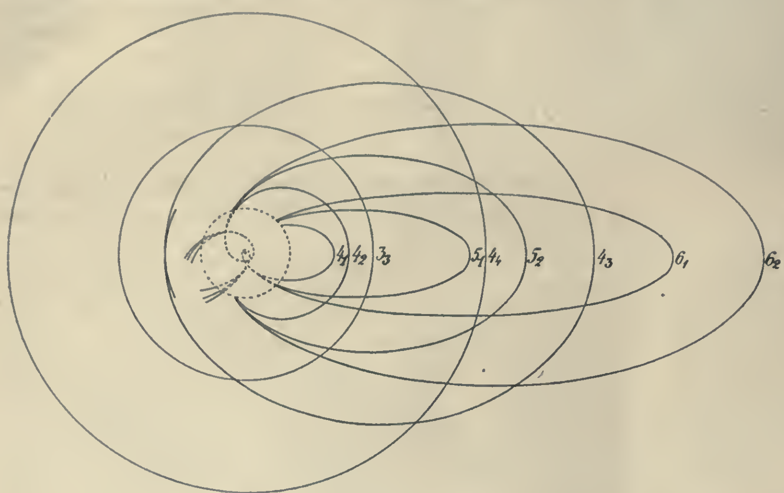

Fig. 8.

The Natural System of the Elements.

The ideas of the origin of spectra outlined in the preceding have furnished the basis for a theory of the structure of the atoms of the elements which has shown itself suitable for a general interpretation of the main features of the properties of the elements, as exhibited in the natural system. This theory is based primarily on considerations of the manner in which the atom can be imagined to be built up by the capture and binding of electrons to the nucleus, one by one. As we have seen, the optical spectra of elements provide us with evidence on the progress of the last steps in this building up process.

An insight into the kind of information that the closer investigation of the spectra has provided in this respect may be obtained from Fig. 8, which gives a diagrammatic representation of the orbital motion in the stationary states corresponding to the emission of the arc-spectrum of potassium. The curves show the form of the orbits described in the stationary states by the last electron captured in the potassium atom, and they can be considered as stages in the process whereby the 19th electron is bound after the 18 previous electrons have already been bound in their normal orbits. In order not to complicate the figure, no attempt has been made to draw any of the orbits of these inner electrons, but the region in which they move is enclosed by a dotted circle. In an atom with several electrons the orbits will, in general, have a complicated character. Because of the symmetrical nature of the field of force about the nucleus, however, the motion of each single electron can be approximately described as a plane periodic motion on which is superimposed a uniform rotation in the plane of the orbit. The orbit of each electron will therefore be to a first approximation doubly periodic, and will be fixed by two quantum numbers, as are the stationary states in a hydrogen atom when the relativity precession is taken into account.

In Fig. 8, as in Fig. 5, the electron orbits are marked with the symbol n_k, where n is the principal quantum number and k the subordinate quantum number. While for the initial states of the binding process, where the quantum numbers are large, the orbit of the last electron captured lies completely outside of those of the previously bound electrons, this is not the case for the last stages. Thus, in the potassium atom, the electron orbits with subordinate quantum numbers 2 and 1 will, as indicated in the figure, penetrate partly into the inner region. Because of this circumstance, the orbits will deviate very greatly from a simple Kepler motion, since they will consist of a series of successive outer loops that have the same size and form, but each of which is turned through an appreciable angle relative to the preceding one. Of these outer loops only one is shown in the figure. Each of them coincides very nearly with a piece of a Kepler ellipse, and they are connected, as indicated, by a series of inner loops of a complicated character in which the electron approaches the nucleus closely. This holds especially for the orbit with subordinate quantum number 1, which, as a closer investigation shows, will approach nearer to the nucleus than any of the previously bound electrons.

On account of this penetration into the inner region, the strength with which an electron in such an orbit is bound to the atom will—in spite of the fact that for the most part it moves in a field of force of the

same character as that surrounding the hydrogen nucleus—be much greater than for an electron in a hydrogen atom that moves in an orbit with the same principal quantum number, the maximum distance of the electron from the nucleus at the same time being considerably less than in such a hydrogen orbit. As we shall see, this feature of the binding process in atoms with many electrons is of essential importance in order to understand the characteristic periodic way in which many properties of the elements as displayed in the natural system vary with the atomic number.

In the accompanying table (Fig. 9) is given a summary of the results concerning the structure of

Fig. 9.

the atoms of the elements to which the author has been led by a consideration of successive capture and binding of electrons to the atomic nucleus. The figures before the different elements are the atomic numbers, which give the total number of electrons in the neutral atom. The figures in the different columns give the number of electrons in orbits corresponding to the values of the principal and subordinate quantum numbers standing at the top. In accordance with ordinary usage we will, for the sake of brevity, designate an orbit with principal quantum number n as an n-quantum orbit. The first electron bound in each atom moves in an orbit that corresponds to the normal state of the hydrogen atom with quantum symbol 1_1. In the hydrogen atom there is of course only one electron; but we must assume that in the atoms of other elements the next electron also will be bound in such a 1-quantum orbit of type 1_1. As the table shows, the following electrons are bound in 2-quantum orbits. To begin with, the binding will result in a 2_1 orbit, but later electrons will be bound in 2_2 orbits, until, after binding the first 10 electrons in the atom, we reach a closed configuration of the 2-quantum orbits in which we assume there are four orbits of each type. This configuration is met for the first time in the neutral neon atom, which forms the conclusion of the second period in the system of the elements. When we proceed in this system, the following electrons are bound in 3-quantum orbits, until, after the conclusion of the third period of the system, we encounter for the first time, in elements of the fourth period, electrons in 4-quantum orbits, and so on.

This picture of atomic structure contains many features that were brought forward by the work of earlier investigators. Thus the attempt to interpret the relations between the elements in the natural system by the assumption of a division of the electrons into groups goes as far back as the work of J. J. Thomson in 1904. Later, this view-point was developed chiefly by Kossel (1916), who, moreover, has connected such a grouping with the laws that investigations of X-ray spectra have brought to light.

Also G. R. Lewis and I. Langmuir have sought to account for the relations between the properties of the elements on the basis of a grouping inside the atom. These investigators, however, assumed that the electrons do not move about the nucleus, but occupy positions of equilibrium. In this way, though, no closer relation can be reached between the properties of the elements and the experimental results concerning the constituents of the atoms. Statical positions of equilibrium for the electrons are in fact not possible in cases in which the forces between the electrons and the nucleus even approximately obey the laws that hold for the attractions and repulsions between electrical charges.

The possibility of an interpretation of the properties of the elements on the basis of these latter laws is quite characteristic for the picture of atomic structure developed by means of the quantum theory. As regards this picture, the idea of connecting the grouping with a classification of electron orbits according to increasing quantum numbers was suggested by Moseley's discovery of the laws of X-ray spectra, and by Sommerfeld's work on the fine structure of these spectra. This has been principally emphasised by Vegard, who some years ago in connexion with investigations of X-ray spectra proposed a grouping of electrons in the atoms of the elements, which in many ways shows a likeness to that which is given in the above table.

A satisfactory basis for the further development of this picture of atomic structure has, however, only recently been created by the study of the binding

processes of the electrons in the atom, of which we have experimental evidence in optical spectra, and the characteristic features of which have been elucidated principally by the correspondence principle. It is here an essential circumstance that the restriction on the course of the binding process, which is expressed by the presence of electron orbits with higher quantum numbers in the normal state of the atom, can be naturally connected with the general condition for the occurrence of transitions between stationary states, formulated in that principle.

Another essential feature of the theory is the influence, on the strength of binding and the dimensions of the orbits, of the penetration of the later bound electrons into the region of the earlier bound ones, of which we have seen an example in the discussion of the origin of the potassium spectrum. Indeed, this circumstance may be regarded as the essential cause of the pronounced periodicity in the properties of the elements, in that it implies that the atomic dimensions and chemical properties of homologous substances in the different periods, as, for example, the alkali-metals, show a much greater similarity than that which might be expected from a direct comparison of the orbit of the last electron bound with an orbit of the same quantum number in the hydrogen atom.

The increase of the principal quantum number which we meet when we proceed in the series of the elements, affords also an immediate explanation of the characteristic deviations from simple periodicity which are exhibited by the natural system and are expressed in Fig. 1 by the bracketing of certain series of elements in the later periods. The first time such a deviation is met with is in the 4th period, and the reason for it can be simply illustrated by means of our figure of the orbits of the last electron bound in the atom of potassium, which is the first element in this period. Indeed, in potassium we encounter for the first time in the sequence of the elements a case in which the principal quantum number of the orbit of the last electron bound is, in the normal state of the atom, larger than in one of the earlier stages of the binding process. The normal state corresponds here to a 4_1 orbit, which, because of the penetration into the inner region, corresponds to a much stronger binding of the electron than a 4-quantum orbit in the hydrogen atom. The binding in question is indeed even stronger than for a 2-quantum orbit in the hydrogen atom, and is therefore more than twice as strong as in the circular 3_3 orbit which is situated completely outside the inner region, and for which the strength of the binding differs but little from that for a 3-quantum orbit in hydrogen.

This will not continue to be true, however, when we consider the binding of the 19th electron in substances of higher atomic number, because of the much smaller relative difference between the field of force outside and inside the region of the first eighteen electrons bound. As is shown by the investigation of the spark spectrum of calcium, the binding of the 19th electron in the 4_1 orbit is here but little stronger than in 3_3 orbits, and as soon as we reach scandium, we must assume that the 3_3 orbit will represent the orbit of the 19th electron in the normal state, since this type of orbit will correspond to a stronger binding than a 4_1 orbit. While the group of electrons in 2-quantum orbits has been entirely completed at the end of the 2nd period, the development that the group of 3-quantum orbits undergoes in the course of the 3rd period can therefore only be described as a provisional completion, and, as shown in the table, this electron group will, in the bracketed elements of the 4th period, undergo a stage of further development in which electrons are added to it in 3-quantum orbits.

This development brings in new features, in that the development of the electron group with 4-quantum orbits comes to a standstill, so to speak, until the 3-quantum group has reached its final closed form. Although we are not yet in a position to account in all details for the steps in the gradual development of the 3-quantum electron group, still we can say that with the help of the quantum theory we see at once why it is in the 4th period of the system of the elements that there occur for the first time successive elements with properties that resemble each other as much as the properties of the *iron group*; indeed, we can even understand why these elements show their well-known paramagnetic properties. Without further reference to the quantum theory, Ladenburg had on a previous occasion already suggested the idea of relating the chemical and magnetic properties of these elements with the development of an inner electron group in the atom.

I will not enter into many more details, but only mention that the peculiarities we meet with in the 5th period are explained in much the same way as those in the 4th period. Thus the properties of the bracketed elements in the 5th period as it appears in the table, depend on a stage in the development of the 4-quantum electron group that is initiated by the entrance in the normal state of electrons in 4_3 orbits. In the 6th period, however, we meet new features. In this period we encounter not only a stage of the development of the electron groups with 5- and 6-quantum orbits, but also the final completion of the development of the 4-quantum electron group, which is initiated by the entrance for the first time of electron orbits of the 4_4 type in the normal state of the atom. This development finds its characteristic expression in the occurrence of the peculiar family of elements in the 6th period, known as the *rare-earths*. These show, as we know, a still greater mutual similarity in their chemical properties than the elements of the iron family. This must be ascribed to the fact that we have here to do with the development of an electron group that lies deeper in the atom. It is of interest to note that the theory can also naturally account for the fact that these elements, which resemble each other in so many ways, still show great differences in their magnetic properties.

The idea that the occurrence of the rare-earths depends on the development of an inner electron group has been put forward from different sides. Thus it is found in the work of Vegard, and at the same time as my own work, it was proposed by Bury in connexion with considerations of the systematic relation between the chemical properties and the grouping of the electrons inside the atom from the point of view of Langmuir's static atomic model. While

until now it has not been possible, however, to give any theoretical basis for such a development of an inner group, we see that our extension of the quantum theory provides us with an unforced explanation. Indeed, it is scarcely an exaggeration to say that if the existence of the rare-earths had not been established by direct chemical investigation, the occurrence of a family of elements of this character within the 6th period of the natural system of the elements might have been theoretically predicted.

When we proceed to the 7th period of the system, we meet for the first time with 7-quantum orbits, and we shall expect to find within this period features that are essentially similar to those in the 6th period, in that besides the first stage in the development of the 7-quantum orbits, we must expect to encounter further stages in the development of the group with 6- or 5-quantum orbits. However, it has not been possible directly to confirm this expectation, because only a few elements are known in the beginning of the 7th period. The latter circumstance may be supposed to be intimately connected with the instability of atomic nuclei with large charges, which is expressed in the prevalent radioactivity among elements with high atomic number.

X-ray Spectra and Atomic Constitution.

In the discussion of the conceptions of atomic structure we have hitherto placed the emphasis on the formation of the atom by successive capture of electrons. Our picture would, however, be incomplete without some reference to the confirmation of the theory afforded by the study of X-ray spectra. Since the interruption of Moseley's fundamental researches by his untimely death, the study of these spectra has been continued in a most admirable way by Prof. Siegbahn in Lund. On the basis of the large amount of experimental evidence adduced by him and his collaborators, it has been possible recently to give a classification of X-ray spectra that allows an immediate interpretation on the quantum theory. In the first place it has been possible, just as in the case of the optical spectra, to represent the frequency of each of the X-ray lines as the difference between two out of a manifold of spectral terms characteristic of the element in question. Next, a direct connexion with the atomic theory is obtained by the assumption that each of these spectral terms multiplied by Planck's constant is equal to the work which must be done on the atom to remove one of its inner electrons. In fact, the removal of one of the inner electrons from the completed atom may, in accordance with the above considerations on the formation of atoms by capture of electrons, give rise to transition processes by which the place of the electron removed is taken by an electron belonging to one of the more loosely bound electron groups of the atom, with the result that after the transition an electron will be lacking in this latter group.

The X-ray lines may thus be considered as giving evidence of stages in a process by which the atom undergoes a *reorganisation* after a disturbance in its interior. According to our views on the stability of the electronic configuration such a disturbance must consist in the total removal of electrons from the atom, or at any rate in their transference from normal orbits to orbits of higher quantum numbers than those belonging to completed groups; a circumstance which is clearly illustrated in the characteristic difference between selective absorption in the X-ray region, and that exhibited in the optical region.

The classification of the X-ray spectra, to the achievement of which the above-mentioned work of Sommerfeld and Kossel has contributed materially, has recently made it possible, by means of a closer examination of the manner in which the terms occurring in the X-ray spectra vary with the atomic number, to obtain a very direct test of a number of the theoretical

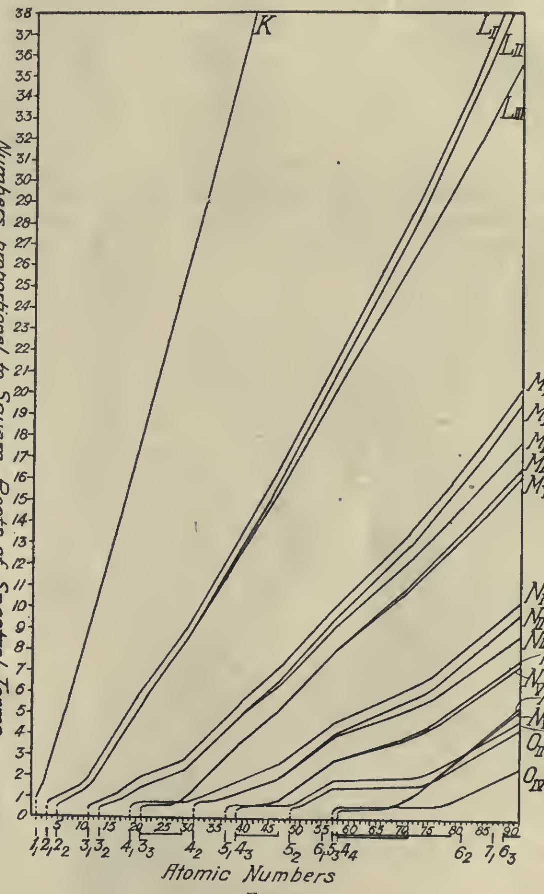

Fig. 10.

conclusions as regards the structure of the atom. In Fig. 10 the abscissæ are the atomic numbers and the ordinates are proportional to the square roots of the spectral terms, while the symbols K, L, M, N, O, for the individual terms refer to the characteristic discontinuities in the selective absorption of the elements for X-rays; these were originally found by Barkla before the discovery of the interference of X-rays in crystals had provided a means for the closer investigation of X-ray spectra. Although the curves generally run very uniformly, they exhibit a number of deviations from uniformity which have been especially brought to light by the recent investigation of Coster, who has for some years worked in Siegbahn's laboratory.

These deviations, the existence of which was not discovered until after the publication of the theory

of atomic structure discussed above, correspond exactly to what one might expect from this theory. At the foot of the figure the vertical lines indicate where, according to the theory, we should first expect, in the normal state of the atom, the occurrence of n_k orbits of the type designated. We see how it has been possible to connect the occurrence of every spectral term with the presence of an electron moving in an orbit of a definite type, to the removal of which this term is supposed to correspond. That in general there corresponds more than one curve to each type of orbit n_k is due to a complication in the spectra which would lead us too far afield to enter into here, and may be attributed to the deviation from the previously described simple type of motion of the electron arising from the interaction of the different electrons within the same group.

The intervals in the system of the elements, in which a further development of an inner electron group takes place because of the entrance into the normal atom of electron orbits of a certain type, are designated in the figure by the horizontal lines, which are drawn between the vertical lines to which the quantum symbols are affixed. It is clear that such a development of an inner group is everywhere reflected in the curves. Particularly the course of the N- and O-curves may be regarded as a direct indication of that stage in the development of the electron groups with 4-quantum orbits of which the occurrence of the rare-earths bears witness. Although the apparent complete absence of a reflection in the X-ray spectra of the complicated relationships exhibited by most other properties of the elements was the typical and important feature of Moseley's discovery, we can recognise, nevertheless, in the light of the progress of the last years, an intimate connexion between the X-ray spectra and the general relationships between the elements within the natural system.

Before concluding this lecture I should like to mention one further point in which X-ray investigations have been of importance for the test of the theory. This concerns the properties of the hitherto unknown element with atomic number 72. On this question opinion has been divided in respect to the conclusions that could be drawn from the relationships within the periodic table, and in many representations of the table a place is left open for this element in the rare-earth family. In Julius Thomsen's representation of the natural system, however, this hypothetical element was given a position homologous to titanium and zirconium in much the same way as in our representation in Fig. 1. Such a relationship must be considered as a necessary consequence of the theory of atomic structure developed above, and is expressed in the table (Fig. 9) by the fact that the electron configurations for titanium and zirconium show the same sort of resemblances and differences as the electron configurations for zirconium and the element with atomic number 72. A corresponding view was proposed by Bury on the basis of his above-mentioned systematic considerations of the connexion between the grouping of the electrons in the atom and the properties of the elements.

Recently, however, a communication was published by Dauvillier announcing the observation of some weak lines in the X-ray spectrum of a preparation containing rare-earths. These were ascribed to an element with atomic number 72 assumed to be identical with an element of the rare-earth family, the existence of which in the preparation used had been presumed by Urbain many years ago. This conclusion would, however, if it could be maintained, place extraordinarily great, if not unsurmountable, difficulties in the way of the theory, since it would claim a change in the strength of the binding of the electrons with the atomic number which seems incompatible with the conditions of the quantum theory. In these circumstances Dr. Coster and Prof. Hevesy, who are both for the time working in Copenhagen, took up a short time ago the problem of testing a preparation of zircon-bearing minerals by X-ray spectroscopic analysis. These investigators have been able to establish the existence in the minerals investigated of appreciable quantities of an element with atomic number 72, the chemical properties of which show a great similarity to those of zirconium and a decided difference from those of the rare-earths.[2]

I hope that I have succeeded in giving a summary of some of the most important results that have been attained in recent years in the field of atomic theory, and I should like, in concluding, to add a few general remarks concerning the view-point from which these results may be judged, and particularly concerning the question of how far, with these results, it is possible to speak of an explanation, in the ordinary sense of the word. By a theoretical explanation of natural phenomena we understand in general a classification of the observations of a certain domain with the help of analogies pertaining to other domains of observation, where one presumably has to do with simpler phenomena. The most that one can demand of a theory is that this classification can be pushed so far that it can contribute to the development of the field of observation by the prediction of new phenomena.

When we consider the atomic theory, we are, however, in the peculiar position that there can be no question of an explanation in this last sense, since here we have to do with phenomena which from the very nature of the case are simpler than in any other field of observation, where the phenomena are always conditioned by the combined action of a large number of atoms. We are therefore obliged to be modest in our demands and content ourselves with concepts which are formal in the sense that they do not provide a visual picture of the sort one is accustomed to require of the explanations with which natural philosophy deals. Bearing this in mind I have sought to convey the impression that the results, on the other hand, fulfil, at least in some degree, the expectations that are entertained of any theory; in fact, I have attempted to show how the development of atomic theory has contributed to the classification of extensive fields of observation, and by its predictions has pointed out the way to the completion of this classification. It is scarcely necessary, however, to emphasise that the theory is yet in a very preliminary stage, and many fundamental questions still await solution.

[2] For the result of the continued work of Coster and Hevesy with the new element, for which they have proposed the name hafnium, the reader may be referred to their letters in NATURE of January 20, February 10 and 24, and April 7.

Training for the Industrial Professions.

IN the formation of the great professional corporations of industrial intellect it is evident that there must be some condition of entry which shall make for a certain uniformity and shall satisfy the requirements of existing members. The essential principle on which all agree is that there must be proof of an adequate education in theory, along with a sufficient and comprehensive training in practice. This combination is ensured in various ways, but for those who aim at securing the hall-mark of inclusion within the appropriate professional institution there is now in Great Britain a scale of reasonably comparable requirements, based in every instance upon a proof of soundness of general and scientific education, with a guarantee at each stage that progressive professional or technical experience is being simultaneously acquired.

Schemes of this type have been adopted by the Institute of Chemistry, and the Institutions of Civil, Mechanical, and Electrical Engineers, among others. Qualification to register as student is given either by success in a special examination held by the institution concerned, or by production of evidence of having passed some recognised equivalent, such as the Matriculation examination of a university; and, in this connexion, it is interesting to note that among the requirements there is now in every case, in addition to a proved knowledge of science, a demand for a good training in English, and, at some stage, for knowledge of one foreign language.

Having thus entered, the student, with increase of experience, is led to further tests, and, with these satisfied and under the personal recommendation of those professionally competent, he may pass forward at appropriate ages to Graduateship, to Associate Membership, and in the end to full Membership of the institution chosen.

The subject-matter of these further examinations is almost entirely technical, and has to deal with the specialised knowledge required for the particular profession; but again, in lieu of this special examination, it is permissible to offer a recognised and approved equivalent in the shape of the degree of an approved university, or the diploma of an approved college. There is, as the student advances in his career, a gradual elimination of demand for those subjects which may be studied mainly for educational training in favour of those which are of direct professional importance.

The course of education and training followed is to give the power both to work and to think, ability not only to carry into performance with intelligence instructions given, but also to see possibilities of new design or process.

The success of this method adopted for the creation of a highly qualified and well-acknowledged directorate has been most evident, conspicuous alike in home employment and in foreign and colonial engagement. Certain broad principles have been laid down and enforced to ensure that a course of study, coupled with practical training properly supervised, has produced a satisfactory and prescribed result, and, in order to maintain for the corporate body a voice of accepted authority, the strictest conditions of admission have been enforced.

Until recently it has been with this part of the problem of training that the great engineering and chemical institutions have been principally concerned. Realising the vast potentialities and responsibilities of their professions, they have rightly demanded from those desirous of entering the highest qualifications obtainable. The direction of scientific industry has risen to demand the fullest knowledge of the relevant sciences; and it is to ensure the possession of this knowledge that each institution, jealous of its entrants, has laid down examinational tests which have been carefully considered by practical experts, and bear considerable weight in the formulation of higher schemes of study.

In every industry, however, it has to be recognised that success comes not alone through the guidance of a trained, well-informed, and open-eyed directorate, but that there must be also an adequate supply of skilled and educated under-officers and men. It is therefore of the greatest interest to notice the recent extension of activity of several of these high professional associations, which, with the assistance and active co-operation of the Board of Education, have now taken within their purview schemes of study and examination whereby opportunity of close association with the professional body is given to those skilled or scientific workers who are ready to devote the time requisite to follow an approved course of theoretical study, which for the National Certificates may be taken in evening or part-time classes.

It is to be hoped that this further advance, recognising unity of interest and consequent inter-dependence between the professional worker and those actually engaged in the operations of production, may lead to the creation of a band of officers of industry, competent to undertake the effective direction of one or more of the many departments into which the fabric of a great industrial undertaking is now divided, or to come forward to take charge at a call of emergency.

There can be no doubt that we have in this new and wider outlook, which has been brought about by wise co-operation of the highest representatives of our great industries with the Board of Education, a possibility of most far-reaching consequence, likely not only to influence with advantage the whole provision of relevant educational opportunity, but also to produce a far wider moral and psychological effect upon the worker, who will in this way be able to see opportunity of clearer relationship within one body between the man of directing professional qualification and himself.

British scientific industry has often in the past suffered from want of this association, and it is to be hoped that other professional institutions with industrial purpose may feel able to follow the enlightened example of those which have instituted a movement likely to bear the best of fruit.

A special feature of the schemes of collaboration so far arranged by the Institution of Mechanical Engineers, the Institution of Electrical Engineers, and the Institute of Chemistry with the Board of Education for the issue of National Certificates and Diplomas is the guarantee of standard vouched for by the appropriate institution in conjunction with the Board, along with the allowance of reasonable variation in arrangement of the subject-matter of the approved courses to ensure satisfaction of the needs of local trade specialisation. The examinations are conducted locally but under the surveillance of appointed central assessors. Certificates and Diplomas thus authenticated should be able to claim world-wide acceptance of value where similar work is required to be undertaken, while the schemes should give to the several institutions a most valuable means of encouragement towards the training of the higher grades of supervisory workers.

Evolution and Christian Faith.

(1) *Evolution and Christian Faith.* By Prof. H. H. Lane. Pp. xi+214. (Princeton: Princeton University Press; London: Oxford University Press, 1923.) 9*s*. net.

(2) *Origin and Evolution of Religion.* By Prof. E. Washburn Hopkins. Pp. v+370. (New Haven: Yale University Press; London: Oxford University Press, 1923.) 15*s*. net.

THE two books before us are of interest not only in themselves but also as illustrating important types of mental activity in America. Both books deal with religion. Yet the author of one is a professor of zoology and of the other a professor of Sanskrit. Prof. Lane writes from the Christian point of view, and combines an expert knowledge of biology with religious earnestness. His work is the outcome of a series of lectures in which he was asked by students to describe the theory of evolution and the salient facts on which it is based, and to discuss the effect of accept-

ance of the theory on "one's views of the Biblical account of Creation and of the Christian religion." Prof. Hopkins, on the other hand, is not a Christian apologist, but plainly sympathises with the religious syncretism which is not uncommon among American intellectuals. He seeks to disclose and, we suggest, sometimes exaggerates likenesses to be found in the advanced religions of mankind. He uses a singularly wide survey of the religious development of humanity to indicate the sort of faith which may emerge from the present clash of creeds and philosophies. He is learned, urbane, and detached.

Though the writers of the two books thus differ widely, they represent parallel developments of a characteristically modern movement. Throughout the nineteenth century there was a continuous battle between science and theology, or, to speak more definitely, between certain assumptions associated with but not essential to the Christian faith and the contradictory conclusions reached by modern investigation. Such a conflict was inevitable, for, as Prof. Gilbert Murray has justly said, the progress of human knowledge has been four times as rapid during the last hundred years as during any century since the Christian era began. The conflict, moreover, could have but one end: it necessarily resulted in the victory of "science." But, however complete the victory, the fact and value of religion remain. So it was to be expected that the victors themselves, once their triumph was assured, would turn to formulate an intellectual basis for religion. As the books before us indicate, they are now making their contribution to the restatement of theology; and theologians, learning from them, are using their own special knowledge for the same purpose.

It is well to insist that each type of specialist is needed for the work. Just as theologians half a century ago were contemptuous of the knowledge won by men of science, so now the latter often fail to realise that from the modern theologian there is much to be learnt. For lack of a theological training, the man of science who is a Christian is always in danger of stumbling into some form of "popular orthodoxy" which the theologian would repudiate. The scholar or man of science, unfamiliar with Christian theology, may easily make false generalisations from isolated statements, and, not seeing the wood for the trees, may lose sight of the essential features of the Christian *Weltanschauung*.

It is necessary to emphasise that Christianity is a synthesis. It is built upon the Gospels and their central Figure; and, of course, behind His teaching lay Jewish ethical monotheism. But the classical Creeds were developed by combining this basis with Greek philosophy and, especially, with ideas derived from Plato. In particular, it is assumed that goodness, beauty, and wisdom are absolute values: that they express the spiritual nature of the universe: that, because they have eternal value, they have eternal existence. The real world is thus the spiritual world, where these values exist eternally; and this world of ours is but an imperfect copy of a perfect archetype. Obviously the Gospel and this philosophico-religious setting form a harmony. Modern Christian theologians contend that this harmonious structure gains in strength when into it the conclusions of modern science are built. If, as we believe, they are right, changes due to modern discovery will not harm the fundamentals of Christianity, though some types of cherished picture-thinking will become obsolete.

(1) We will not attempt to describe Prof. Lane's "Evolution and Christian Faith." The main outlines of his argument will be familiar to all who have given some attention to the subject. As is common with American authors, he pays more regard to works by his own countrymen than to those of British thinkers. He writes clearly and argues fairly; and his book may be commended to those who desire to give to the science-student a clear perception of the inadequacy of materialism as a philosophy. He occasionally stumbles when he ventures outside his own realm of biology. For example, he says that Galileo, after 1632, "was thrown into prison, [and] treated with all the severity which his remorseless persecutors could devise, for the remaining ten years of his life." He obviously derives this statement from Draper's "Conflict between Religion and Science." It is inaccurate. In White's "Warfare of Science with Theology" there is a more exact account, with numerous references, of the persecution of Galileo. It was a deplorable business, but not quite so bad as Prof. Lane suggests.

To take another example, Prof. Lane, in writing of the Genesis accounts of Creation, reveals that Biblical scholarship is to him largely a *terra incognita*. He assumes that Moses is the author of the two cosmogonies of which fragments are preserved; and somewhat naïvely suggests that a modern "interpretation does not in any way convict Moses of ignorance nor deceit." Of course, the familiar first chapter of Genesis is a product of Jewish speculation of the time of the exile; and, though the second account of Creation may be some three centuries earlier, it comes from a document which no unprejudiced scholar would assign to Moses himself.

Prof. Lane does not clearly state his view of the nature of Biblical inspiration; and one might read his book without suspecting that he has any doubts as to the substantial infallibility of Scripture. With

regard to miracles he suggests that they may be "in accord with some higher law of which the human mind can at present, at least, form no conception." But he is led from this legitimate belief to ascribe to Christ "knowledge which infinitely transcends our human powers." Such a view, though common, is heretical, because it impairs the perfect humanity of Christ. The orthodox formula, "very God and very Man," is both more subtle and more reasonable than is popularly realised.

Just as the technical theologian might demur to some of Prof. Lane's teaching, so the physicist might ask him to enunciate "the law of gravitation," which "holds universally in nature." But few who try to cover the ground over which the author moves could escape all its pitfalls. Taken as a whole, his work is an admirable defence of the position that there is no inherent antagonism between Christian theism and the biological doctrine of evolution. In England, save by Roman Catholics or extreme Protestants, the position is now generally accepted by Christians. Moreover, an increasing number of men of science recognise that evolution affords no secure basis for a materialist philosophy. As an interpretation of the facts presented by Nature and human nature, such systems as Haeckel's materialistic monism are inadequate. Philosophers, using all such facts, normally work towards theism or pantheism. English divines have not been slow to point out that the conclusions of modern science harmonise with the Christian outlook on human life and with the Christian interpretation of the universe. But in America there is still a widespread belief that evolution is destructive of the Christian faith.

Prof. Lane gives some amazing illustrations of the extent and effects of this mistaken fear. Mr. W. J. Bryan has led a campaign against evolution, the echoes of which are still reverberating from press and pulpit in the Middle Western States. Great religious congresses have declared evolution a "heresy." "The state of Kentucky came near enacting a law forbidding the teaching of this scientific doctrine in any school supported by public funds." A generation ago it seemed as if the Western World had finally escaped from the temper which led the Inquisition to hand over Giordano Bruno to be burnt. But the spectacle is now before us of a great democracy aflame with religious prejudice. Naturally, religion is being gravely harmed. Extreme Protestant and Roman Catholic seminaries get their supply of enthusiastic recruits, for fanaticism breeds a certain type of faith and devotion. But young men whose minds are open to the thought of the time are distracted or repelled by the conflict around them. Some believe their religious teachers; accept the view that evolution makes atheists—and become atheists. Others naturally resolve to find elsewhere than in the Christian ministry an outlet for their aspirations.

Doubtless many causes contribute to the religious obscurantism prevalent in America. But it is safe to say that one of the most effective is the bold, and sometimes extravagant, philosophico-religious speculation common in American universities. Partly owing to its mixed population and partly because of its geographical position between Europe and Asia, America produces learned men less sensitive than our own to the value of the Christian tradition. They try to survey with impartial superiority the varied manifestations of the religious spirit in Europe and Asia. They are aware of the intellectual poverty of much popular Christian thought. They view with cold and contemptuous detachment the strange and novel cults of which their own country is singularly prolific. They are attracted by the philosophical subtlety of Hindu speculation, and probably have no first-hand experience of the moral corruptions which pantheism shelters. The general effect of their teaching is rightly felt by ordinary men and women to be destructive of all religious certainty.

(2) Prof. Hopkins's "Origin and Evolution of Religion" is the sort of book to excite reactionary prejudice, for the half-educated reader will merely perceive that its values are wrong. To us it appears a mixture of wide learning and confused thought. The author gives an illuminating account of primitive religion as disclosed by modern anthropological research. As professor of Sanskrit at Yale, he naturally writes with authority of the development of Aryan religious ideas in India. He describes at length the evolution of Buddhism. He sketches the conflict, among the Greeks and Hebrews, between primitive religious beliefs and finer types of philosophico-spiritual understanding. "In Greece, a moral philosophy gradually developed apart from the gods. The Hebrews alone united ethics, religion, and an anti-polytheistic philosophy." He gives an account of the evolution of Christian theology which we find unsatisfactory. In his pages the complex movement which united Neo-Platonism to the Gospels is inadequately presented. Probably misrepresentation is inevitable in an author who can write that "it makes no religious difference whether God is regarded as essentially quite apart from or immanent in nature."

Prof. Hopkins, setting aside the Christian belief in absolute values, gives us utilitarian ethics. "The ethical law in respect of taking life is not *Thou shalt not kill* but *Thou shalt kill*, when killing aids the group. That is the reason why it was right to kill

an Englishman in 1776 and a German in 1918 till November 11." Obviously it is impossible to place such teaching in the Christian scheme. But we do not see how it can be reconciled with the position which Prof. Hopkins finally reaches. "Whether called divine or not, one controlling conscious intelligence appears to exert its will towards the realisation of a moral ideal in which we participate." It seems to us that, if the implications of this conclusion are developed, the main postulates of Christian Platonism must be accepted. Such, at any rate, is the contention of some of our foremost English theologians. Men of science, interested in these matters, should study the *Confessio Fidei* which appears at the beginning of the second series of Dean Inge's "Outspoken Essays." They will find there no scientific obscurantism, and, at the same time, a powerful discrimination between the ethico-religious values of theism and pantheism which Prof. Hopkins might study with advantage.

E. W. BARNES.

Bacteria of the Soil.

Agricultural Bacteriology. By Prof. J. E. Greaves. Pp. 437. (London: Constable and Co. Ltd., 1922.) 21*s.* net.

WITH the large increase in agricultural experiment stations throughout the world, and with the growth in size and activity of such older stations as Rothamsted within the last ten years, there has been produced a vast amount of work dealing with the activities of bacteria in the soil, their relations to soil fertility, and the influence upon them of external conditions such as manurial treatment. Much of this work is disconnected, and suffers from a want of correlation with our knowledge of related subjects. There is a need, therefore, for text-books that will set in order the facts now established and point out the lines of development which our present knowledge is opening up.

Prof. Greaves has produced a book designed, not primarily for the expert, but to stimulate curiosity and inquiry in the student. The first portion is devoted to general bacteriology, discussing the morphology and schemes for the classification of bacteria, their chemical composition and physiology, and the influence upon them of external conditions such as temperature, heat, disinfectants, and salts. This is a very desirable arrangement, especially since the branches of applied bacteriology are to-day suffering from the backwardness of our knowledge of the fundamental problems of pure bacteriology. One feels, indeed, that the author would have done well to have emphasised more strongly the directions in which such knowledge is most needed. He has also included in this general section such subjects as the influence of heat, volatile antiseptics, and arsenic on soil bacterial activities. It would seem more reasonable to deal with these matters in connexion with the soil population, since the facts do not indicate a simple issue between the soil bacteria and the disinfecting agent.

The middle portion of the book deals with the soil flora and its activities, such as the production of ammonia and nitrate, the fixation of nitrogen, denitrification, cellulose decomposition, and the solvent action of bacterial metabolic products on soil minerals. At the conclusion are chapters on the relation of bacteria to water supply, sewage, dairying, food preservation, and various technical processes.

The completeness with which our present knowledge has been presented, varies very greatly in different parts of the volume. The most interesting part of the work is that which deals with the fixation of atmospheric nitrogen, where the main aspects of the subject are well put forward. Unfortunately, however, reference is omitted to some fundamental work on the soil micro-population without a knowledge of which the student cannot obtain a true picture of the activities of bacteria in the soil. Essential to this, for example, is some knowledge of recent work on the relation between bacterial numbers and the active protozoan fauna in field soil. In criticising Russell and Hutchinson's phagocyte theory of partial sterilisation, the author even states that "the work of Russell and Hutchinson does not consider the probability of the protozoa being in the soil as cysts." The existence of active protozoa in the soil was discovered by Martin and Lewin at Rothamsted in 1915, and, in the protozoology department, initiated there to investigate this subject, it has since been shown by Cutler and Crump (1920) that the numbers of active amœbæ and flagellates in field soil change from day to day, and that the increase and decrease of certain active amœbæ bear an inverse relationship to changes in bacterial numbers. The connexion between active protozoa and bacterial numbers is, therefore, established, with the consequent probability that, if this equilibrium be upset by some partial sterilisation process, such changes would ensue as were found by Russell and Hutchinson.

Again, in connexion with the production of ammonia from organic nitrogen compounds in the soil, the author does not emphasise how important is the nature of the energy supply available to the ammonifying organisms, which, apparently, are equally able to derive their energy from a non-nitrogenous source, and, where such compounds are available, may even assimilate ammonia and nitrate, thus causing a temporary loss of these compounds from the soil. The importance of this factor was pointed out by Doryland (1916). In the chapter on the decomposition of cellulose, there is no

reference to the work, at Rothamsted, of Hutchinson and Clayton (1919) on the remarkable *Spirochæta cytophaga*, which led to a study by Hutchinson and Richards of aerobic cellulose decomposition as a whole, resulting in a process, now in practical use, for making artificial farmyard manure from straw.

It is admittedly impossible, in a book of this type, to cover all the work on bacteria in relation to agriculture, but, as this is the case, it would seem a pity that valuable space should have been given to such unimportant matter as, for example, the fanciful history of an individual phosphorus atom (p. 185).

The author has decided not to give references to literature quoted, but instead gives three or four papers with each chapter, which are selected as containing fuller references to the subject. In many cases, however, a student would find it difficult and sometimes impossible to trace the literature of work mentioned in the text. This, in the reviewer's opinion, is a serious defect. A text-book of this type, even though it be intended merely " to stimulate curiosity and inquiry," should, if it fulfils this purpose, lead the inquirer to a more intimate study of the subject, and, as stepping-stones to this more complete knowledge, good references to literature are essential.

There are some statements in the book which, through inadvertence, are incorrect or misleading. Thus it is stated (p. 35) that nitrogen-fixing bacteria must have atmospheric nitrogen and oxygen, but, in fact, some are anaerobic and probably all can utilise combined nitrogen where this is available. Again, the author says (p. 34) that " *most* plants cannot use nitrogen in the form of ammonia; it must be in the form of nitrates." But Hutchinson and Miller (1909) and also Prianischnikov (1916) found a considerable variety of plants that could utilise ammonia, and Hesselmann (1917) found forest soils that were devoid of bacteria capable of producing nitrate. These examples could be multiplied. Prof. Greaves has planned an interesting book, which, however, could be much more useful if some of the less important matter were omitted so that the present extent of our knowledge could be more completely covered. H. G. Thornton.

The Latin Works of Geber.

Die Alchemie des Geber. Übersetzt und erklärt von Dr. Ernst Darmstädter. Pp. x+202. (Berlin: Julius Springer, 1922.) 10*s*.

In this book Dr. Darmstädter has given a German translation of the " Summa perfectionis," " Liber de investigatione perfectionis," " Liber de inventione veritatis sive perfectionis," " Liber fornacum," and " Testamentum Geberi," mainly, as regards the first four, from the edition published at Nuremberg in 1541. The texts of the Testamentum employed are those of the editions of Venice, 1542, and Danzig, 1682. The translator has included also an introduction on Geber and his writings, a list of manuscripts and printed editions of the Latin works, and many notes, together with a short glossary of alchemical terms. The book is illustrated with excellent reproductions of six plates from the 1541 edition, two from Libavius's Alchymia, 1606, and one other, of distillation, from a book published in 1512.

While Dr. Darmstädter's book is a noteworthy contribution to the voluminous literature on Geber, it cannot be said to have treated the matter comprehensively or altogether accurately. The questions of the identity of Geber and of the origin of his works " sind noch zu beantworten und sollen den Inhalt einer besonderen Arbeit bilden," but the author adopts uncritically the position of Berthelot and von Lippmann and dismisses, on entirely inadequate grounds, the possibility that " Geber " may be Jabir ibn Hayyan. The evidence on this point has recently been discussed in Nature (February 10, p. 191 and February 17, p. 219), but it may be well here again to emphasise that practically the only facts mentioned in the Latin works which have not so far been found in the Arabic works of Jabir ibn Hayyan are the preparation of *aqua regia*, *aqua fortis*, and silver nitrate. It is significant that even such an unimportant fact as the blue copper flame, noted by Geber (p. 66), is also described by Jabir ibn Hayyan (" Book of Properties," chap. 3), and, I believe, in no other work earlier than the thirteenth century.

The list of manuscripts is incomplete. Thus there is a fourteenth-century MS. of the " Summa " in the Bodleian, and another in Trinity College, Cambridge, while in the Hunterian Library at Glasgow there is one of the thirteenth century. Dr. Darmstädter knew of no MSS. of the " Liber fornacum "; there is, however, one which professes to be a translation by Roger Bacon, in the British Museum (*Sloane*, 1118, ff. 60-71). It is probably of the fifteenth century. At Gonville and Caius College there is a fifteenth-century MS. of the " Secreta Secretorum in opere solaris et lunaris," attributed to Geber; the title corresponds with that of a work by Jabir ibn Hayyan, the " Kitāb sirr al-Asrār." The Bodleian MS., " Ad laudem Socratis dixit Geber " (fifteenth century), calls to mind the work of Jabir entitled " Musahhihat Socrat," mentioned in the " Kitāb al-Fihrist," but now lost.

The translation is good and in general accurate, but it seems a pity that it was made from printed editions and not from early manuscripts, when it would have been much more authoritative. The notes are clear and scholarly; the information they contain is largely

derived from Prof. E. O. von Lippmann's "Entstehung und Ausbreitung der Alchemie." In view of the fact that copies of Geber's works are scarce, the present edition will be welcome to all chemists, for Geber had a pleasant style and his writings are full of interest and still worth reading. It is satisfactory, too, to see that the book is to be sold in England at what appears to be a very modest price.

It is perhaps fitting, in concluding this review, to ask the pertinent (but, it is to be hoped, not impertinent) question: "If Geber was not Jabir ibn Hayyan, who was he?"

E. J. HOLMYARD.

The Living Plant.

Botany of the Living Plant. By Prof. F. O. Bower. Second edition. Pp. xii+634. (London: Macmillan and Co., Ltd., 1923.) 25*s.* net.

THE publication of a second edition of Prof. F. O. Bower's excellent "Botany of the Living Plant" less than four years after the appearance of the original work shows that the volume has received the recognition it so justly deserved. This new edition has undergone a good deal of alteration, much of which has been made by the author as a result of criticisms and friendly suggestions.

The changes have certainly improved the book to a very considerable extent, the most important being the treatment of the Cryptogams and Gymnosperms, which occupy the second half of the work. Instead of these plants being arranged with the Coniferæ at the beginning and the fungi, bacteria, and algæ at the end, Prof. Bower now begins the second half with a very useful chapter on evolution, homoplasy, homology, and analogy. This new chapter serves to introduce the progressive series of plant forms the life histories of which are traced in evolutionary series from the simplest Thallophyta to the complex Gymnosperms in the chapters which follow.

The series of chapters, culminating in the ferns and conifers, is followed now quite logically by the chapters on "Alternation of Generations and the Land Habit" and on "Sex and Heredity," which, though they have very properly been transposed, come at the end of the book as formerly.

The appendix (A) on types of floral construction in Angiosperms then follows, and forms a useful introduction to the systematic study of plants; and appendix (B) on vegetable food-stuffs is followed by a carefully compiled index and glossary; these complete the volume as in the first edition.

Several minor alterations have been noticed in comparing the two editions, and they are all distinct improvements: in particular the new chapter on "The Living Cell" deserves special notice. This chapter is a very useful addition, since, in the first edition, the general physiological conditions of the plant cell were not treated so fully as is necessary for a proper understanding of that continuous living system of which the plant body consists.

In this new edition, after describing fully the cellular construction of plants, the structure of the several living units which compose the plant body follows naturally, and allows the succeeding chapters on the tissues of stem, leaf, and root, and on general physiology, to be fully appreciated.

Specialists in one branch of botany or another may perhaps feel that sufficient space has not been given to one or other aspect of botanical science, which now covers so wide a field; but, as Prof. Bower very justly says in his preface to the first edition, "No attempt has been made after encyclopedic writing," and we feel that it is well for the student who is to be introduced to the plant as a living organism that the author has confined himself so admirably to the object on which he embarked, and has succeeded in producing a book which is certainly the standard British work on general botany.

Our Bookshelf.

War: Its Nature, Cause, and Cure. By G. Lowes Dickinson. Pp. 155. (London: G. Allen and Unwin, Ltd., 1923.) 4*s.* 6*d.* net.

WITH his usual convincing sincerity, Mr. Dickinson sets out the unanswerable case against war. He appeals especially to younger men to realise what the nations have done, what they are doing now, and what it must all lead to unless the issue is honestly faced, and every one makes up his own mind clearly as to whether he wants war or not. For readers of NATURE as such, the book would therefore have no immediate interest were it not that the author brings into some emphasis the relations of science and men of science to warfare.

If mankind does not end war, war will end mankind. If this has not been true in the past, it is true now because modern war is linked with modern science, which, if the chief hope for the world, is also its chief menace. Men of science have in consequence more than average weight in deciding whether war is to continue or not; and some at any rate of them will not fail to be moved by Mr. Dickinson's appeal to bring all the prestige and intelligence of natural knowledge on to the side of those who mean to end war. He suggests that chemists and physicists and others who might be concerned should collectively and internationally announce that they did not propose to communicate to governments anything which would be useful in war—an impossible proposition, as the author would know if he had more acquaintance with the history and mode of progress of scientific

knowledge and with the ingenuity with which men who are determined to kill will degrade every scrap of human information to their end. But it is no impossible chimera that men of science should refuse to help in applying their special knowledge to the prosecution of war, and should let it be known that if war is to continue it must be waged without their assistance. Mr. Dickinson, at any rate, will be satisfied if they will read his book, reflect honestly and plainly on the implications of what he has to say, and bring to their conclusions the same independence and clarity that they apply to their daily work. It is difficult to believe that there will be many who after doing this will still be on the side of war. A. E. B.

British Museum (Natural History). Guide to the Exhibition Galleries of Geology and Palæontology. Pp. 64. (London: British Museum (Natural History), 1923.) 1*s*.

THE Keeper of Geology, in his preface to this small book, says, "It is merely a guide, not an introduction to the study of fossils." Those familiar with official scientific publications may appreciate the modesty and wisdom of this statement. But intelligent members of the general public, for whom the book has been written, will soon find that the statement errs on the side of diffidence; they will say, "This is not merely a guide, but a remarkably good guide"; and, taking it with them round the galleries, may discover to their advantage that it is one of the best short introductions to the study of fossils in the English language.

The casual visitor to these magnificent geological collections is often bewildered by the multitude of objects and oppressed by the strangeness of nomenclature. With this guide he will be led in an orderly and logical manner through the whole series of exhibits, his attention being directed only to outstanding features of each group; the systematic names are explained in everyday terms and the essential characters of the fossils are made clear, while no opportunity is lost of showing how the forms of these extinct creatures throw light upon their habits and phylogeny. Thus a great deal of sound information is woven into a readable story, which does not neglect human interest but links up the fossils with their discoverers or with some apt reference to literature or history. Who will not be tempted after reading of Thomas Hawkins to look up his descriptions of the hunt for Ichthyosauri, or to renew an acquaintance with "The Chambered Nautilus" of Oliver Wendell Holmes?

Dr. F. A. Bather, the author, has rendered good service to palæontology and to the public at a time when there was never more need for a straightforward introduction to this valuable and fascinating branch of knowledge, understandable by the ordinary man. J. A. H.

The Microscope: A Practical Hand-book. By L. Wright. Enlarged and rewritten by Dr. A. H. Drew. Pp. 287. (London: Religious Tract Society, n.d.) 5*s*. net.

IN the earlier chapters of this book an excellent account is given of the fundamental principles of optics, the practical optics of the microscope, and of the simple and compound microscopes. The salient features of a number of microscope stands by various makers are detailed and many of the instruments figured. Accessories, dark ground illumination, and methods for testing objectives are also described, together with manipulation and photo-micrography. Separate chapters are then devoted to the various objects of microscopy, such as pond and insect life, animal and vegetable histology, and others, with directions for manipulating and mounting them. The sections on staining have been revised and brought up-to-date and new stains and methods introduced. Thus, directions are given for the demonstration of mitochondria, the Golgi apparatus, karyokinesis, etc. The book contains a mass of accurate information, is profusely illustrated, and can be cordially recommended, not only to the beginner, but also to many who have already passed the elementary stage.

Organic Chemistry: or, Chemistry of the Carbon Compounds. By Victor von Richter. Edited by Prof. R. Anschütz and Dr. H. Meerwein. Vol. 3: Heterocyclic Compounds. Translated from the Eleventh German edition by Dr. E. E. Fournier d'Albe. Pp. xviii+326. (London: Kegan Paul and Co., Ltd.; Philadelphia: P. Blakiston's Son and Co., 1923.) 25*s*. net.

THE present volume, like the two preceding ones, is a useful guide to organic chemistry for general laboratory use, but it suffers from the same defect in being out-of-date. Heterocyclic derivatives of phosphorus and arsenic, for example, do not appear in the index, nor, apparently, in the text. References to English work are given to the German *Centralblatt*, without the names of the authors, and one gathers the entirely incorrect impression that organic chemical work is confined almost exclusively to Germany. The nomenclature is not always that adopted in England; the quinoline nucleus is numbered according to a system which has not been in use in this country for many years. The best method of preparation of a substance is not specially indicated, and not enough distinction is made between methods of *preparation* and methods of *formation*. Until English chemists supply their own needs, however, such books will have to be used.

Atoms. By Prof. Jean Perrin. Authorised translation by D. Ll. Hammick. Second English edition revised. Pp. xv+231. (London, Bombay and Sydney: Constable and Co., Ltd., 1923.) 8*s*. 6*d*. net.

THE second English edition of Prof. Perrin's inimitable book has been carefully revised in accordance with the eleventh French edition, and a certain amount of new matter added for the first time. The latter covers, for example, Perrin's new theory of radiation and chemical change, and there is a complete list of isotopes at the end of the book. Of the original work it is scarcely necessary to say anything: it has become a scientific classic, and is at the same time an account of the latest views on the subject. The translation has been well done, and the meaning is clearly rendered. In one or two cases (*e.g.* p. 112) "ou bien" has been translated "better," which is not its meaning in the examples cited.

Letters to the Editor.

The Crossed-Orbit Model of Helium.

THE spectrum formula

$$\nu = \mathrm{N}\left[3 - \frac{7}{4\pi}\mathrm{F}\left(\sin\frac{i}{2}\right)\right], \quad . \quad . \quad . \quad (a)$$

proposed for helium in my letter of March 1 (NATURE of April 28, p. 567), was shown to yield, for $-\cos i = \frac{1}{2}$, the correct ionisation potential and, for $\frac{4}{5}$, $\frac{2}{3}$, $\frac{3}{5}$, $\frac{5}{9}$, the four Lyman lines; with that corresponding to the former as the limit. The deduction of this formula (on lines by no means classical) and the attitude to be taken with regard to the "negative" results obtained in the meantime by Dr. Kramers by means of classical mechanics (*Zeits. f. Physik*, 13, 312) have been fully explained in a paper appearing in the June issue of the *Astrophys. Journal*, and need not be repeated here. The purpose of this letter is to point out some further peculiarities of the formula (a) as such, which will be seen to bring order into the apparently queer correlation given before.

If the simple rational values of $-\cos i$ are ordered in descending magnitude, namely,

$$\tfrac{4}{5}\ (\tfrac{3}{4})\ \tfrac{2}{3}\ (\tfrac{5}{8})\ \tfrac{3}{5}\ (\tfrac{4}{7})\ \tfrac{5}{9}, \quad . \quad . \quad . \quad (b)$$

every second, bracketed one, covers no observed line, while the others represent orderly the first four members, $m=1$, etc., of the Lyman series $o\mathrm{S} - m\mathrm{P}$. Extrapolating the regular sequence of the last three fractions by

$$(\tfrac{6}{11}) \text{ and } \tfrac{7}{13},$$

one would expect the former to cover no line and the latter to represent the line $o\mathrm{S} - 5\mathrm{P}$, which, though hitherto not observed, can be expected with confidence. Now, with Lyman's oS and the usual 5P, this line should lie at $\lambda_5 = 512{\cdot}1$, while formula (a) gives, for $\cos i = -7/13$, $\lambda = 512{\cdot}3$. Again, turning to the left-hand end of the sequence (b), the next fraction $\frac{5}{6}$ naturally suggested itself as worth trying. For this value of $-\cos i$ ($i/2 = 73{\cdot}221°$, $\mathrm{F} = 2{\cdot}6642$) formula (a) gives $\lambda = 601{\cdot}2$, which is very close indeed to the "single line at $600{\cdot}5 \pm 0{\cdot}3$," repeatedly obtained by Lyman. As I understand from Prof. Lyman himself, he feels reasonably certain that it is genuine and that it belongs to the spectrum of helium. Moreover, from the semi-empirical point of view, the "combination" line $o\mathrm{S} - 1\mathrm{S} = 198{,}300 - 32{,}033$ would lie at $\lambda = 601{\cdot}3$, which is still closer to our result.

Thus, gathering the scattered items, we have, as an extension of (b), the following correlation (in which the bracketed numbers cover no observed lines):

$$\begin{array}{c|cccccccccccc} \tfrac{5}{6} & \tfrac{4}{5} & (\tfrac{3}{4}) & \tfrac{2}{3} & (\tfrac{5}{8}) & \tfrac{3}{5} & (\tfrac{4}{7}) & \tfrac{5}{9} & (\tfrac{6}{11}) & \tfrac{7}{13} & \ldots & \tfrac{1}{2}. \\ o\mathrm{S}-1\mathrm{S} & \lambda_1 & & \lambda_2 & & \lambda_3 & & \lambda_4 & & \lambda_5 & & \lambda_\infty \end{array} \quad . \quad (c)$$

Notice that, according to Prof. Lyman, the arc spectrum of He contains no lines in addition to those here covered. The regular intermittency of (c), so far as the members $o\mathrm{S} - m\mathrm{P}$ are concerned, is manifest. The position of $o\mathrm{S} - 1\mathrm{S}$—the "queer" line, as Dr. Compton of Princeton called it—is correspondingly queer. Yet even this, though only a combination line, fits into the further remarkable regularity of the whole sequence (c), to wit, that the differences between the successive fractions are all of the form $1/np$, thus $5{\cdot}5 - 4{\cdot}6 = 1$, $4{\cdot}4 - 3{\cdot}5 = 1$, $3{\cdot}3 - 4{\cdot}2 = 1$, and so on. This curious feature was first noticed by my friend Prof. A. S. Eve of Montreal only after the whole array (c) was spread over the black-board in a recent lecture at the Bureau of Standards. It may thus be said to have grown out spontaneously, and certainly did not influence the writer in constructing the proposed formula.

So long as intra-atomic dynamics is awaiting its final shaping from modern groping attempts at a suitable modification of ordinary mechanics, every such regularity of correlation, no matter how "magical" in appearance, seems worthy of noticing, as a possibly helpful hint how to alter the old laws for intra-atomic purposes. LUDWIK SILBERSTEIN.

Symmetry of Calcium Thiosulphate Hexahydrate.

CALCIUM thiosulphate hexahydrate, $CaS_2O_3 \cdot 6H_2O$, is usually quoted in works on crystallography as an example of the triclinic asymmetric class, C_1^1—perhaps as the only known crystal which definitely represents this type of structure. It is described in Tutton's "Crystallography" (new edition, p. 280, old edition, p. 285), and, in more detail, in Groth's "Chemische Krystallographie," vol. 2, p. 676. In the latter we read

$CaS_2O_3 \cdot 6H_2O$. Asymmetric. Sp. gr. 1·872.

$$a : b : c = 0{\cdot}7828 : 1 : 1{\cdot}5170.$$

$$\alpha = 72°\ 30', \quad \beta = 98°\ 34', \quad \gamma = 92°\ 45\tfrac{3}{4}'.$$

The process by which symmetrical crystals are built up from less symmetrical material has been recently described by Sir William Bragg ("The Significance of Crystal Structure," Trans. Chem. Soc., 1922, vol. 121) and G. Shearer ("The Relation between Molecular and Crystal Symmetry as shown by X-ray Crystal Analysis," Proc. Phys. Soc., February, 1923). In the latter paper the author suggests that Nature never uses more molecules than are absolutely necessary for the purpose; that is, no more than N asymmetrical molecules will be used in the construction of a crystal of "symmetry-number" N, or, if the symmetry of the molecules be that of some class n, then no more than N/n will be used. Up to the present this hypothesis seems to be justified. In all organic crystals that have been examined in Sir William Bragg's laboratory not one has yet been found to contradict it. In all cases there has been no evidence to show that polymers of chemical molecules have been used, but, on the contrary, abundant evidence to show that the ultimate structural bodies correspond to the simple chemical molecules. Furthermore, it has been shown that, in general, the symmetry of a crystal is of a higher type than that of the molecules from which it is built—a rule which seems to be almost universally true. Especially with complex molecules does Nature resort to the device of combining a molecule with its digonal or its enantiomorph before using them to construct a Bravais lattice.

In view of these considerations it seemed very probable that, should a truly asymmetric crystal be obtained, its space-lattice would be found to be constructed of asymmetric groups of atoms corresponding to single chemical molecules; that is, it would be found to contain only one molecule per fundamental cell. Such a case seemed to be presented by $CaS_2O_3 \cdot 6H_2O$, and, indeed, it was expected that X-rays would show it to be a simple triclinic lattice of single asymmetrical molecules, obeying, of course, the law of rational indices, but exhibiting no symmetry operation beyond that of identity.

By means of the Bragg ionisation spectrometer an examination of this crystal has been carried out. The results are in full agreement with a *two-molecule* cell (Table I.).

TABLE I.

$1\bar{1}\bar{1}$	4·65	4·65	55	45	15	..

Of course, we might now argue that this does not prove anything, since the theory of space-groups takes no cognisance of the structure of the ultimate asymmetric units, but confines itself to the number and relative orientations of these necessary to produce one or other of the 230 homogeneous point-systems. Theoretically, it is just as easy to conceive of a crystal of the class C_1^1 being built from a two-molecule cell as from a one-molecule cell. In the former case it would simply mean that to construct an asymmetric lattice, Nature, at variance with her usual procedure, had used an asymmetric polymer of the chemical molecule instead of the single molecule.

In spite of this, it is here suggested that $CaS_2O_3 . 6H_2O$ is *not*, after all, the unique example of the triclinic asymmetric class, but only one of the many examples of the pinakoidal class C_i^1. The following reasons are given for this: (1) in all complex crystals so far examined, the ultimate structural unit has proved to correspond to the chemical molecule; and (2) there is a mass of evidence to show that the crystal symmetry, as deduced from a study of facial development and etched figures, is often of a lower type than the true structural symmetry as deduced from X-ray data (and generally confirmed by other indications). An interesting paper dealing with this subject has recently been contributed by E. T. Wherry, *Am. Journ. Science*, September 1922; but as a few well-known examples of this pseudo-symmetry we may cite potassium chloride (cubic holohedral, *not* pentagonal icositetrahedral), diamond (cubic holohedral, not hexakis-tetrahedral), cuprite (cubic holohedral, not pentagonal icositetrahedral), wulfenite (tetragonal holohedral, not pyramidal), and ammonium chloride (not pentagonal icositetrahedral, but either hexakis-tetrahedral or holohedral). The last-named is especially interesting since it has been examined by several workers. It now seems conclusive that its structure is what was originally suggested (Bragg, "X-rays and Crystal-Structure," p. 158), that it belongs not to an enantiomorphous class of the cubic system but to a class showing planes of symmetry (probably hexakis-tetrahedral—see R. W. G. Wyckoff, *Am. Journ. Science*, December 1922). With such crystals as these we must class many of the co-ordination-compounds of the type $\{Me'''(X_3'')\}R_3 . nH_2O$ examined by F. M. Jaeger ("Recherches sur le principe de Pasteur," *Rec. d. trav. chim. d. P. B.*, tome xxxviii.). Though substances of this type are very strongly optically active, many of their crystals appear to lack the characteristics of the enantiomorphous classes.

These few examples will suffice to show that it has become unsafe to argue from form development and etched figures, that, for example, the hitherto accepted evidence for placing $CaS_2O_3 . 6H_2O$ in the asymmetric class is not trustworthy. It is becoming increasingly clear that the boundary conditions of a crystal are often so different from the conditions obtaining inside the structure that not only the growth but also the inverse process of solution (etched figures) leads to a definite *under*-estimate (in most cases) of the real internal symmetry.

On the other hand, all the evidence so far is now in favour of placing $CaS_2O_3 . 6H_2O$ in the pinakoidal class, since the cell contains two molecules, and, by analogy with other known structures, these may be taken to be centro-symmetrical with respect to each other. It is true that this latter supposition cannot yet be proved, because in the triclinic system the two molecules, provided they are so orientated as to be centro-symmetrical with respect to each other, may occupy any relative positions in the cell. However, X-rays certainly show that the *smallest* cell which repeats through space contains two chemical molecules, and that there is no evidence that they are alike. The inference then is that they are the inversions of each other and that the complete structure is in reality centro-symmetrical. In this connexion it should be noted that two other triclinic crystals have also been thoroughly examined, namely, anhydrous racemic acid and racemic acid monohydrate. If only for chemical reasons, there is no doubt that these two crystals are built of molecules which are inverse to each other, and X-rays again show that the smallest cell which repeats through space contains *two* chemical molecules only.

If we knew more about the intensities of X-ray reflections, we should be able to prove that the two molecules in the cell of $CaS_2O_3 . 6H_2O$ are inverse to each other, but for the present this is impossible. For the same reason, no attempt has been made to fix the atomic positions in the cell. An examination of the optical properties would be highly desirable, with the view of detecting rotatory polarisation, should any be shown. Such a test would then be practically decisive.

For the preparation of the crystals which have been examined, I wish to express my indebtedness to Mr. C. P. Proctor, of the Chemical Laboratory, University of Birmingham.

A Method of Photographing the Disintegration of Atoms and of Testing the Stability of Atoms by the Use of High-speed Alpha Particles.

WHILE the experimental work of Rutherford demonstrates the disintegration of the nuclei of the atoms of six elements of odd atomic number to give long-range hydrogen nuclei, it does not show whether shorter-range products of disintegration are emitted. It occurred to one of the writers several years ago

that the photographic method of C. T. R. Wilson would be the best means easily available of actually testing the stability of the nuclei of atoms for the different types of disintegration, particularly when the particles emitted have a short range. In the earlier applications of this method polonium has been used almost exclusively as the source of α-particles. The α-particles thus emitted have a relatively small kinetic energy, so the evidence obtained from the photographs is not of much value in its bearing on nuclear stability. The writers have therefore used the high-speed α-particles from thorium C′, with a velocity of $2 \cdot 05 \times 10^9$ cm./sec., or 0·688 c.

In an earlier letter (NATURE, January 27, p. 114) we gave a photograph showing the sharpest collision obtained in ten thousand exposures, the α-particle being turned through an angle of about 125°. The sharpest collision given by Blackett (Proc. Roy. Soc. A, 103, p. 79 (plate 3)) is less sharp, since the α-particle is turned through an angle of 110° or less. Fig. 1 shows two views, taken from directions perpendicular to each other, of a collision between an α-particle and the nucleus of an atom of air. This is the sharpest collision we have obtained by taking twenty-one thousand photographs. In this case the α-particle is turned through an angle of 165°, so that the lines which show the track of the α-particle before and after the collision exhibit a sharp angle equal to 15°.

In an ordinary collision the initial track of the α-particle splits into two branches beyond the point where the collision takes place. One of these is due to the rebounding α-particle, and the other to the forward track of the nucleus which is hit. If this nucleus were to disintegrate during the collision or quickly enough afterward, an additional track would emerge from the point of collision, and this would be due to the fragment, such as a hydrogen nucleus or an α-particle, which is ejected. It is possible, too, that electrons or other additional particles might

FIG. 1.—α-ray track which splits into three branches after a collision. The upward loop in the initial track is due to the diffusion of electrons out of a region partly robbed of water vapour by an earlier track.

also be emitted, so that the track might split into even more than three branches. However, all of the particles thrown off may not produce visible tracks. Thus the tracks given by high-speed electrons are faint, and are sometimes invisible in parts of the gas which have been robbed of their water vapour.

The extremely sharp collision photographed in Fig. 1 exhibits the very interesting phenomenon that the original track splits into *three branches at the point of collision, which is exactly the characteristic to be expected if the bombarded atom disintegrates*. The film on which the photograph was taken shows the lines at the point of collision much more plainly than the reproduction, and a study of the black lines on the film as seen under the microscope indicates that the third particle is shot diagonally upward, exactly from the point of collision as nearly as this can be determined by a microscopic examination of both of the views (taken at right angles). The great relative brightness of the track of this particle is due to the fact that the camera gets a "head-on" view. The discussion of the momentum relations will be left to a more complete paper, but it may be stated that, so far as we are able to determine, the collision does not exhibit conservation of momentum if the particle which shoots upward is left out of account. If this could be definitely proved it would give remarkably substantial evidence, in addition to that of the number of tracks, that a disintegration has occurred.

FIG. 2.—Nearly parallel curved tracks of particles ejected backward. Probably these are due to electrons.

Bumstead, and later Wilson, have secured photographs of the tracks of δ-rays, supposedly due to electrons pulled out of the non-nuclear systems of the atoms through which the α-particle passes. These tracks are extremely short, and are most easily seen when the expansion in the ionisation chamber is not too high. Fig. 2 shows an entirely new type of secondary track. Here what appear to be electrons are thrown out a great many times as far as in the δ-rays, and in a different direction. The two electron tracks curve upward, show a backward motion, and are remarkably close to being parallel. They differ so markedly from those of the δ-rays that they may be considered as a different type of ray. They may be designated as ζ-rays.

Altogether about eighty thousand tracks have been photographed. From the assumed dimensions of a molecule in air it may be estimated that each α-particle passes through between 100 and 200 thousand atoms, so approximately 10 billion atoms have been shot through, with the result that only three nuclear collisions have resulted in which the initial α-particle has been given a *retrograde* motion. In only one of these, as illustrated in Fig. 1, has the collision been very direct. The photographs show many other interesting relations which cannot be discussed here.

WILLIAM D. HARKINS.
R. W. RYAN.

Science and Economics.

MAY I bring this correspondence back to earth by recalling that I based my deduction that no one even pretended to understand the present economic system upon the fact that, although the age is as far ahead of any preceding epoch in the science of producing wealth as it is in astronomy or chemistry, yet millions of

folk are (1) without decent means of subsistence, (2) idle? My impression, in directing the attention of scientific men to this problem, was that a very little of the original thought which they habitually devote to more abstract questions would give the solution of this one. But I scarcely bargained for NATURE being so widely read as to render it necessary for me to meet philosophical arguments.

Mr. Leisenring, who devotes four of your valuable columns to a defence and elucidation of the philosophy of the system challenged, looks characteristically for a change of ideals to bring about the readjustment which he admits to be most urgent. Now, what was there reprehensible about the ideals of the nineteenth century? Was it not the ideas which were upside down? I need not follow him in his fanciful descriptions of and deductions from my views, though, indeed, it is a novelty for readers of NATURE to be told that a proposal to ascertain the physical basis of economics is tantamount to an attempt to baulk human evolution and to impose upon man an inferior order of existence. Surely most of us thought that the ascertainment and understanding of the laws of Nature were preliminaries to governing and directing them to human ends. Eastern proverbs notwithstanding, the achievements of one age in this field are the starting-point of those in the next. Your correspondent seems to confuse the methods of science with those that apply to the government and direction of men at the hustings, on the battlefield, in the Courts and theatres, and by the general Press. Such confusion is widespread, and the results of scientific progress need to be safeguarded and made "fool-proof" from the interference of the humane genius.

However, I cordially agree, and have myself remarked, that the original great rulers of the world were under no such vulgar delusions as are current to-day about gold and money. Mr. H. O. Weller recently told me that Kublai Khan's currency was of *papier mâché*, and that some of his coinage is extant. The important point to them was not what the coin was made of, but whether they issued it. My description of the present financial system as counterfeit was in allusion to the fact that less than 1 per cent of the money functioning as such is authorised by the King and issued by the Royal Mint. Olden-time rulers issued the currency, but that also is "inverted." Since millions are (1) destitute, (2) idle, the presumption is that, although many may understand perfectly the art of making money, the reason which makes this, necessarily, a royal prerogative is now not understood by any one.

I am sorry if the laws of evolution preclude, and the annals of history do not record, an absolute innovation, and I cannot defend the word "absolute," since innovations are necessarily relative. But it will be in the memory of many that recently there was a war, and, before a shot had been fired, a moratorium terminated the old financial system. The public credit became necessary to maintain solvency. Though it would be rash to predict that in the future the old system may not be restored in a modified form, it does not appear imminent. On my analysis it is difficult to see how the public credit can be dispensed with. For what else is behind the colossal accumulation of indebtedness which we have inherited from the age of irreproachable ideals and inverted ideas? The honest intentions to meet "promises to pay," and the ability to perform what this industrial age and its ideals demand, were quietly transferred to the broader shoulders of the public during the hubbub preceding Armageddon. The rope has been lengthened and its end attached to a larger neck. The ultimate basis of credit has been widened, but from the point of view of physics it is still credulity.

The spontaneous increment of wealth is subject to the laws of thermodynamics, like all conversion of natural resources, whether to useful or useless forms. You may *measure* it, so long as it exists to measure, by the spontaneous increment of debt, and the philosophy of usury is much more interesting no doubt than thermodynamics, and is likely to counteract the unemployment engendered by the achievements of the latter science, even among those who, like your correspondent, find life tends to become uninteresting. So you can measure the horse-power of an engine by braking it, or the content of a pot, not only by filling it when empty but also by emptying it if it be full. For any other purpose than mere measurement, however, to try to fill a leaky pot, or to run an engine with brakes on, is foolish. So long as wealth production was not understood, the virtues of gold or usury or other magical influence could be invoked. But that time is past. Until Mr. Lane Fox Pitt came to the rescue with his euphemistic theory of psychological inversion (NATURE, May 19, p. 670), I found it difficult to discuss these matters without giving offence. I fear, however, that a system of economics based on a philosophy of usury imagines the process of emptying to be a reversible cyclic process—that the pot is emptied back into the clouds rather than into the ocean.

To come to the concrete, I have a method of producing, more economically than any other person, the goods that the community desire. Is that a collateral security? No: but if I have a block of receipts for the wealth blown up in the Napoleonic wars, known as Consols, or any other gilt-edged security, I can obtain the community's credit at any time, without the necessity of being able to produce anything at all. The process is almost too incredibly Gilbertian to discuss in NATURE. But clearly there is something very different in practice from primitive philosophic conceptions of credit, since the power to pledge the community's credit is vested, not with those with ability to produce but with those with ability to consume, though the powers of consumption may date back to some remote forerunner of the modern patriot in the Napoleonic era, and the goods consumed then may have already been paid for many times over.

The use of mechanical energy made possible an enormous, if finite, increase of the *revenue* of wealth. This annual *revenue*, by the simple process of dividing it by the rate of interest, say 0·05, is multiplied by twenty or "capitalised." The capital, however, differs from the earlier forms of credit, such as land or factories (that is, until they become obsolete and tumble down), in being non-existent, and this difference I submit is fundamental. It is also under the necessity of increasing according to an exponential law without limit, which is physically absurd.

FREDERICK SODDY.

[We regret to be unable to devote space to further correspondence on this subject.—EDITOR, NATURE.]

A Puzzle Paper Band.

PROF. C. V. BOYS's puzzle (NATURE, June 9, p. 774) is a deal less puzzling (as he doubtless knows) if we begin it at the other end. Instead of making the long belt with its two loops which he describes, and then trying to reduce it to the well-known half-twist "double surface" (cf. *e.g.* Forsyth's "Differential Geometry," p. 296) of double thickness, let us begin by laying two strips of paper one on the other;

then with a half-twist bring the ends together, and fasten the corresponding ends each to each. Our half-twist will have brought one end of the lower strip into contact with the other end of the upper strip; and what we then obtain, on opening out, is the long loop (or "worble," to use Maxwell's word) with its two curls, which Prof. Boys starts with. We have simply *split* into two sheets our original one-sided, one-edged surface, and obtained a new *bifacial* surface thereby, precisely as Mr. B. M. Sen explains in his recent paper on "Double Surfaces" in the Proc. Lond. Math. Soc.

We may vary the experiment by starting with three sheets (or with five) instead of two. The middle sheet or strip, joining on to itself, will always remain the half-twisted loop, the unifacial surface; while each adjacent pair of strips will constitute a bifacial surface such as Prof. Boys describes. The median loop will involve, or link together, all the others; but the manner in which these latter interlace with one another is more complicated. The problem of how to split an anchor-ring into two rings, interlinked with one another, is a simple corollary.

It is somewhat curious at first sight, but obvious after all, that we arrive at precisely the same result whether we split our sheet, or cut it longitudinally. Begin with one broad strip, joining its ends together into the half-twisted unifacial surface; then make one continuous longitudinal cut, not far from the edge. This single cut gives us two complete loops, one being the border and the other the median zone of our broad strip. The median band has its properties unaltered; it is still the half-twist unifacial surface, only narrower than before. The other, on which our scissors have bestowed a second edge, is the bifacial surface which Prof. Boys calls his "puzzle band."

Active Hydrogen by Electrolysis.

WENDT and Landauer (Jour. Amer. Chem. Soc., March, 1922, p. 513) failed to get any evidence for the presence of active hydrogen, generated by the action of an acid on a metal, or by the electrolysis of a solution of KOH. Similar results were also obtained by Y. Venkataramaiah (Proc. Sci. Assoc. Maharaja's College, Vizianagram, July 1921, p. 2). We have repeated the experiments, and find that hydrogen is actually activated when a conducting solution is electrolysed. We electrolysed a solution of dilute sulphuric acid, employing a platinum tube with a large number of pin-holes bored in it, and using a current varying from 3 to 15 amperes. While the electrolysis was going on, compressed nitrogen was bubbled through the solution, through the platinum electrode, to see if any ammonia were formed, as Wendt and Landauer found that active hydrogen combines with nitrogen to form ammonia. After a run of nearly twelve hours, the presence of ammonia was tested in the resulting solution. The result was positive.

Another method was also tried, using an iron tube as an electrode. It is known that nascent hydrogen diffuses through metals like iron even at ordinary temperatures. So it was found convenient to diffuse nascent hydrogen through the iron tube and test for the presence of active hydrogen by drawing it over cold powdered sulphur, the presence of hydrogen sulphide being tested for with a lead acetate paper. Here also a positive result was found.

The experiments with a metal and an acid are not yet successful. The failure in the case of the experiments of Wendt and Landauer, in our opinion, is due not only to the difficulties in removing the spray but also to the action of active hydrogen on the spray itself. Certain preliminary experiments conducted by us show that active hydrogen is decomposed by the spray with the formation of hydrogen peroxide.

It is a pleasure to note from the latest number of NATURE to hand (May 5, p. 600), that Prof. A. C. Grubb has succeeded by an ingenious experiment in demonstrating the presence of active hydrogen in the hydrogen generated by the action of hydrochloric acid on magnesium.

The Transfinite Ordinals of the Second Class.

THERE is a theorem in the transfinite calculus that any ascending sequence of ordinal numbers of the second class has a limit which is also of the second class. This theorem is important, being wanted to prove that the aggregate of these ordinals is unenumerable.

Now consider the set of numbers $1, 2, 3, \omega, \omega+1, \omega+2, \omega.2, \omega.2+1, \omega^2, \omega^2+1$, etc. The mode of formation is that each number exceeds the preceding one by unity, except that if the plan we are following leads us to a limit we write down only a finite number of numbers according to that plan, and then write down the limit and the limit increased by unity, and so on. The set is normally ordered, and each element has an immediate predecessor, whence we easily see that it is a sequence. But it cannot have any limit in the second class, for if the limit is α the sequence must contain α and $\alpha+1$.

Does this contradiction with the first theorem show that the ordinals of the second class form an "inconsistent" aggregate? It differs from that of the Burali-Forti paradox in that we do not assume that our aggregate has an ordinal number before we get the contradiction. It agrees with it in that no contradiction arises if we consider segments only of the aggregate of ordinals.

Shakespeare and the Indian Meteors of 1592.

WITH reference to Mr. Denning's remark in NATURE, June 23, p. 848, I beg leave to point out that the word in Persian for west, namely *khāwar*, also means east, and so it may be that the passage in the Akbarnama means that the meteors were travelling from east to west and not from west to east.

Dean Inge lately observed in a lecture that there was a mystery about what Shakespeare did in the last five years of his life. May it not be that he was travelling in Europe or on the high seas when he saw so many stars shoot madly from their spheres ("Midsummer-Night's Dream," Act II., Scene II.)? There is another allusion to meteors, "Yon fiery o's and eyes of light," in Act III., Scene II., where Lysander speaks of Helena's eyes. This seems to show that Shakespeare's mind was running upon stars and meteors.

I may mention that in a letter to me Sir Sydney Lee seemed to say that there was something in my suggestion, and referred to another topical allusion to natural phenomena in "Romeo and Juliet."

H. BEVERIDGE.

The Production of Single Metallic Crystals and some of their Properties.

By Prof. H. C. H. CARPENTER, F.R.S.

METALS and alloys are composed of aggregates of crystals. These do not, as a rule, possess plane faces, that is, the external forms of crystals. They

FIG. 1.—Showing diminishing size of crystals with increase of strain in the parallel portion of the testpieces. By permission of the Institute of Metals.

are joined together at boundaries which have been produced by the meeting of a number of crystals growing simultaneously, and are usually irregular in outline. It is generally assumed that on cooling, crystallisation starts in the liquid metal or alloy from a number of centres, and proceeds with a velocity and in a manner characteristic of the metal and the conditions under which it has been cooled. The resulting boundaries may approximate to plane surfaces, but are more usually curved and irregular. These crystals are called "allotriomorphic" to distinguish them from "idiomorphic" crystals, which do possess plane faces and are characteristic of most mineral substances and artificially prepared salts. Moreover, they are usually very small and cannot be distinguished without the aid of a microscope. It is true, that in the case of large castings weighing many tons, crystals of several cubic inches capacity have been formed and afterwards isolated. The great majority of metals and alloys, however, which have been cast and hot-worked, have from 150 to 300 crystals to the linear inch, corresponding to from 3,375,000 to 27,000,000 crystals in a cubic inch. Frequently the size is even smaller, especially in the case of steels. The crystals are still more minute in severely drawn wires, and from figures given by Sykes it appears that in molybdenum wire there may be as many as 5000 to the linear inch.

The properties of metals and alloys are the properties of these aggregates of minute crystals. Sauveur was the first investigator to show, about eleven years ago, that by carefully straining and afterwards heating metals, much larger crystals could be produced, and he suggested that there was a critical stress which produced the largest crystals. Later, other investigators, notably Rüder, Chappell, Jeffries, and Hanson, showed that if a metal was locally deformed and then heated, exceptionally large crystals were formed at some distance from the point at which the strain is most severe. About two years ago Miss Elam and the writer succeeded in converting the whole of the parallel portion of aluminium testpieces, whether in the form of sheets or bars, into a single crystal, which indeed extended for some distance up into the curved shoulders of the testpieces, forming an irregular boundary line. The crystals varied in volume from 0·5 to 2·0 cubic inches, and it has been possible to compare some of their properties with those of the aggregates of small crystals, of which this metal is usually composed. Experiments have also been carried out with iron, copper, silver, and tin, but with less success, although in all cases it has been possible to grow crystals very much larger than those contained in the original metal.

In the production of large crystals of aluminium the adjustment between mechanical strain and the temperature of heating is extremely important. This point is clearly brought out in Fig. 1, which shows how the crystal size may be varied in aluminium according to the degree of strain. The eight test-pieces shown, after a preliminary heat treatment to

remove work-hardness and render the crystals equiaxed, were subjected to degrees of tensile strain varying from two to ten per cent. extension on three inches of the parallel portion of the testpiece. After this they were all heated to 550° C. and kept thus for six hours. Finally, they were etched in a ten per cent. solution of sodium hydrate. It will be seen that the crystals in the testpiece extended two per cent. are very coarse, and that as the strain is increased the crystal size diminishes until at ten per cent. it has become quite small. But there is a further point to be noted, namely, that in all the eight cases shown, large crystals have also formed in the broad heads of the testpieces, where the strain must have been less.

The problem which we set ourselves was to convert the crystals, numbering about 1,687,000, in the parallel portion of a testpiece 4 in. × 1 in. × 0·125 in., into a single crystal. Three treatments, two thermal and one mechanical, are necessary. The testpiece in the original condition was cold-rolled, and as a result the crystals were very much elongated and worked into one another. It had first to be heated so that it might be completely softened and new equiaxed crystals of approximately uniform size produced. The most suitable temperature was found to be 550° C. and the time six hours. It had next to be strained to the required amount, which was equivalent to a tensile strain of 2·4 tons per square inch. Finally, it had to be heated so that the potentiality of growth conferred by strain could be brought fully into operation. This was a somewhat lengthy operation, and involved a heat treatment beginning at 450° C. and finishing at 600° C. over a period of about 100 hours. After these treatments, on an average about one testpiece in four is converted into a single crystal over the parallel portion. Sometimes this space is occupied by two, three, or even four crystals, but never by more than that.

The production of these very large crystals has enabled us to determine the tensile properties of single crystals and compare them with those of the aggregates of minute crystals of which such bars are usually composed. In the latter case very uniform results are obtained, the ultimate stress varying from 4·5 to 4·7 tons per square inch, and the percentage extension on three inches being from 36 to 38. The values obtained in tests of specimens consisting of single crystals varied, however, from 2·80 to 4·08 tons per square inch, while the extension varied from 34 to 86 per cent. measured on three inches. These variations in properties were accompanied by differences in the method of stretching and the types of fracture which have provided a means of classifying them.

Speaking broadly, five types may be distinguished. In certain cases the testpieces narrowed in breadth gradually from the shoulders towards the fracture, and the metal necked sometimes almost to a point. In other cases the testpiece remained broad, losing sometimes only one per cent. in breadth, but became very thin. In the third case the testpiece both narrowed and thinned uniformly, and a noticeable feature of this type is the sloping of the sides, so that the section after pulling is no longer a right-angled parallelogram but one with acute and obtuse angles. Slip bands were usually well marked, and were inclined to the axis at different angles. In the fourth type the testpieces not only narrowed and thinned but in addition necked at the fracture, and in all cases a sideways slip was evident. In the fifth type may be included all the testpieces which produced twin crystals on being pulled. No signs of these were visible before stress was applied. In some cases only a few twins resulted, while in others the testpiece was twinned all over. In every case the testpiece buckled and crumpled to a certain extent, owing to the shifting of portions of the sheet into a twinning position. These differences in the method of distortion and fracture are due to differences in the original orientation of the crystal in the testpiece.

Monocrystalline testpieces were also prepared in round bars of diameter 0·564 and 0·798 of an inch

FIG. 2.—Fractured testpieces of single crystals in round bars, showing how in each case the bar draws down in one dimension and produces a wedge-shaped (double-grooved) fracture. By permission of the Institute of Metals.

respectively. The deformation of these testpieces under tensile stress was very remarkable, and deserves special mention. On one hand, a bar consisting of the usual aggregate of small crystals drew down with a roughening of the surface, the maintenance of a circular cross section, and a cup-and-cone fracture. On the other hand, the single crystals flattened very much in one dimension, whereas the other dimension differed but little from the original diameter of the bar, and the end result was not a cup-and-cone fracture but a double groove. The bar when subjected to tensile stress slipped principally on one plane, which subsequent investigations by Mr. G. I. Taylor and Miss C. F. Elam have shown to be an octahedral plane. When it began to break it drew down sharply in the same direction in which it had thinned, and a lens-shaped area was formed. As the bar pulled apart this became flatter and flatter; it parted first at each side and then in the middle. The final result was a curious double-grooved fracture with flow lines. Fig. 2 shows the fractured testpieces of five single

crystals in round bars. In each case the two fractured halves are shown, one placed with the broad and the other with the narrow side facing the camera.

A word must be said about the crystallography of aluminium. Hull was the first to investigate the structure of aluminium crystals in a finely crystalline aggregate by X-ray analysis, and he concluded that the pattern thus obtained corresponds to a face-centred cubic lattice, *i.e.* the grouping of the atoms is such that there is one at each corner of the cube, and one in the centre of each face, making a total of fourteen in all. This corresponds, as Colonel Belaiew has recently pointed out, to an octahedron situated within a cube. Sir William Bragg and Dr. Müller have kindly examined our single crystals, and find that they conform to the same pattern. They belong, therefore, to the cubic system, and must have properties consistent with those of that group which possesses the highest degree of symmetry both external and internal. Investigations of the crystals in this system indicate that as regards certain properties they are isotropic, while as regards others they are anisotropic. In the former category come the properties of conducting light, heat, electricity, and expansion. In the latter are grouped elasticity, cohesion, and conduction of sound. In such cases, however, the properties are closely related to the symmetry, since the maximum and minimum values have been found to coincide with the axes of symmetry.

Accordingly, the variations in the tensile properties of the testpieces which have been described are due to differences of cohesion in different planes which do not all contain the same number of atoms. Although the single crystals obtained in the sheet and bars were formed in the same shaped testpieces in both categories, it was obvious that their original orientation relative to the axis of the testpiece varied considerably. Indeed, it may not have been precisely the same in any two of the cases tested. The shape of the testpiece alters when stress is applied, since slip and deformation take place only on certain planes, and the changes in shape observed correspond to the attempt of the crystal to accommodate itself to the stress. Such changes were much greater in some tests than in others.

It is not possible within the limits of this article to discuss the two questions, (1) why abnormally large crystals form on heating after a small deformation, and gradually decrease in size as the deformation increases; and (2), to take the extreme case, why, after a particular degree of deformation, it is possible to form a single crystal from an aggregate of several millions. Those interested in the matter may be referred to the author's original publications with Miss Elam.[1] It may, however, be stated that the conditions for the production of a single crystal in a testpiece consisting of the usual aggregate of small crystals are considered by us to be, that every crystal in the complex must be strained a certain amount, and that one of them is strained rather more than the rest. This particular crystal may be regarded as being in the condition of critical strain, and ultimately all the other crystals align themselves upon it after sufficient heating. When this condition is realised, the testpiece consists of a single crystal. We have taken up the experimental investigation of the deformation of the testpiece by X-ray analysis, and are hoping that the result of this will show what it is that happens when a testpiece is strained to the critical amount and subsequently heated.

[1] Journal of the Institute of Metals, No. 2, 1920, pp. 85-131. Proceedings of the Royal Society, V. 100a, pp. 329-353. Journal of the Iron and Steel Institute, No. 1, 1923.

The Royal Asiatic Society.

By F. E. PARGITER.

THE Royal Asiatic Society of Great Britain and Ireland was founded in London on March 15, 1823, by the distinguished Sanskrit scholar, Henry Thomas Colebrooke, supported by others interested in Oriental matters, to investigate (as he announced) the history, civil polity, institutions, customs, languages, literature, and science, ancient and modern, of all countries in Asia. This removed the reproach that, while similar societies had been formed at Calcutta, Bombay, Madras, Paris, and elsewhere, Great Britain had done nothing. The charter was granted on August 11, 1824, and under it the Society is governed by a council of twenty-five members, including the president, director, vice-presidents, and other officers, elected annually at general meetings.

The Society was well supported by the East India Company and many eminent men, and prospered and developed its activities. It appointed a "Committee of Correspondence," which embarked on far-spread measures to receive and communicate information about Asiatic matters. From the copious donations that it received it began a library and a museum. To utilise the Oriental MSS. collected in English libraries it established the "Oriental Translation Committee and Fund" in 1828, to publish translations of approved works in Oriental languages, and this was liberally supported, and published thirty volumes in the next four years. The scheme included measures to benefit Asia and Europe materially; hence, when trade with India and China was thrown open in 1833–34, the Society formed a "Committee of Agriculture and Commerce" in 1836, and this collected valuable information about coffee, sugar, opium, and other important commercial products and their improvement. The Society published three quarto volumes of "Transactions," containing papers read before it, in 1827, 1830, and 1833, and began an annual "Journal" in 8vo form in 1834.

The early enthusiasm, however, gradually declined; the membership fell and the financial position caused anxiety. Then came the time of the Cuneiform discoveries by Major (afterwards Sir) Henry Rawlinson, who found the great Behistun and other inscriptions in Persia, eclipsing those reported by earlier travellers. He communicated them to the Society in 1838, solved the problem of their decipherment in 1844, and announced his results in 1846. These were received by the public with much incredulity, but the Society

gave him its cordial support and set apart certain volumes of the Journal for their publication. Opinion turned after a time, and the Society became the centre of a great literary movement. His work, however, never reached completion in those volumes, because excavations by Botta, Layard, and others at Nineveh and Babylon brought out overwhelming material; new duties trenched on his time, and other scholars finished what he had so well begun.

Notwithstanding the interest of these revelations, the Society's condition remained anxious, for local societies in the East appropriated much local inquiry; its efforts to aid commerce became exhausted, and it developed more towards learned research, while Oriental studies attracted little public interest. The committees of correspondence, of Oriental translation, and of agriculture and commerce gradually fell into neglect, and a later effort to revive them had but transient success. The East India Company had generously subsidised the Society, and the loss of its patronage on its abolition in 1858 caused discouragement. The Government after some vacillation continued the subsidy, yet the Society's fortunes still continued low. It changed its abode in 1869, and through want of room made over its museum to the India Office.

The tide turned, however, when Mr. Vaux became secretary in 1877 and devoted himself to the Society's welfare, and more interest in Oriental studies began to be manifested then among the educated. The late Prof. Rhys Davids became secretary from 1887 to 1905 and edited the Journal, and enhanced the improvement. The Society's course since then has been one of steady expansion and influence, and its Journal has risen to acknowledged excellence with a wide and attractive range of subjects. The membership consists of those "resident" within fifty miles from Charing Cross and "non-residents," and also thirty honorary members elected from among eminent foreign scholars.

To reward British erudition the "Gold Medal Fund" was inaugurated in memory of Queen Victoria's Jubilee, and the medal was awarded in 1897 to Prof. Cowell, and since then triennially. Two other funds were established in 1903, the "Public Schools' Gold Medal Fund" and the "Prize Publications Fund." Under the former a prize medal has been awarded yearly on an essay on some Oriental subject in competition among the boys of the public schools. A new "Oriental Translation Fund" was started privately in 1891 and transferred to the Society afterwards, and it began a "Monograph Fund" in 1902. By these three funds many treatises have been issued, and the proceeds of the sale of published books provide the means of printing fresh works. Thus the Society encourages Oriental research, honours Oriental learning, and makes the results public, free of expense to the authors. Another fund, the Forlong Fund, is managed by the Society for the benefit of students at the School of Oriental Languages.

The Society is now established at 74 Grosvenor Street, London, W., and completed its hundredth year on March 15 last. It has issued a centenary volume, displaying its history and the achievements of its members in research, and will celebrate the event by a reunion of Orientalists and festivities on July 17-20. It has a very large and comprehensive library of about 30,000 volumes, important collections of MSS. in many Oriental languages, portraits and busts of eminent members, and valuable objects of antiquity and art. Its most outstanding figures have been its three directors, H. T. Colebrooke (1823–37), Prof. H. H. Wilson (1837–60), and Sir H. Rawlinson (1862–95), and its late president, Lord Reay (1893–1921).

The Journal abounds with articles elucidating all the subjects mentioned in the inaugural discourse regarding all the countries of Asia and those in Africa into which Mohammedanism overflowed, and India has occupied as much attention as all the other countries combined. Archæology has been a leading subject, especially since exploration has brought ancient inscriptions and other material to light from Asia Minor to Further India, and the old texts have become available for study. The Society's representations have largely contributed to archæological enterprise in India. Ancient remains have been examined, inscriptions deciphered, coins read, language and literature investigated, and religion studied. The researches have been so varied, that it is impossible to speak of them here except in general terms. They have not only amplified what was known of the ancient world, but have also reconstructed kingdoms and history that had vanished, disclosed much of the course of civilisation and religion through Asia, and revealed unknown languages that have perished.

Obituary.

Prof. John Chiene.

JOHN CHIENE, late professor of surgery in the University of Edinburgh, to which chair he had succeeded on the death of James Spence in 1882, and held for twenty-eight years, died on May 29 at the age of eighty. Chiene does not claim a record in this journal on account of original scientific work—for scientific inquiry was not much in his line—but he was deeply impressed with the importance of it, and, though not himself an experimenter, he set up in the University the first teaching laboratory of bacteriology and surgical pathology in the United Kingdom. To quote the words of his pupil Sir Harold Stiles, who now occupies the chair once held by Syme and Lister, "Chiene set the example, in the academic teaching of surgery, of cultivating the subject as a science so that its art might be better taught and promoted. . . . He spared neither time nor money to encourage research by his assistants."

Chiene may be said to have belonged to the school of anatomical surgeons; but he had been Syme's house-surgeon and John Goodsir's demonstrator, and from both of these distinguished men he inherited the habit of scientific thought and logical expression. He was a very successful lecturer on operative and systematic surgery in the extra-mural school, and in this way

prepared himself for his still greater success as a university professor.

When Lister came back to Edinburgh from Glasgow in 1869, the feud between the followers of Syme and those of Simpson was simmering out, but by no means forgotten. At that time John Chiene and John Duncan were the most prominent younger surgeons in that city. Both were among Lister's adherents, but Chiene was more than a mere adherent; he became at once a devoted disciple. Every day found him working and studying in Lister's wards, and as years went on he was more and more closely associated with Lister's work.

During his nine years' stay in Edinburgh, Lister was acquiring a world-wide reputation; but among his colleagues he met with sharp criticism from his opponents and only lukewarm support from his friends. Even Annandale, his successor in the chair of clinical surgery, though professedly a convert to the antiseptic doctrine, was not altogether successful in practising it. It was, therefore, most important when Lister went to London in 1878 that some trusty follower should remain in Edinburgh to keep the torch burning there, as Sir Hector Cameron was manfully doing in Glasgow. That trusty follower was found in Chiene. He was now in a very influential position, and he advocated the cause of antiseptic surgery by example and precept with great success until the younger men, Lister's pupils and his own—now themselves middle-aged—had succeeded to the various University chairs and hospital appointments; by which time Lister's principles, though not the details of his practice, had come to be recognised as orthodox and universally followed.

Edinburgh would, of course, like the rest of the world, have become fully enlightened in due time, but it can scarcely be doubted that the period of twilight would have been more prolonged if it had not been for Chiene's whole-hearted and persevering efforts.

Dr. W. d'E. Emery.

By the death of Dr. Walter d'Este Emery on June 19, pathology has lost a keen disciple, and his acquaintances a loyal friend. Emery was a distinguished student of Queen's University, Birmingham, and St. Bartholomew's Hospital, London. After junior appointments held at his schools, he became assistant bacteriologist to the Laboratories of the Royal Colleges of Physicians and Surgeons. Later, he was lecturer on pathology and bacteriology in the University of Birmingham and Hunterian professor at the Royal College of Surgeons. Coming to London, he held various appointments, finally being made lecturer on pathology and bacteriology, and director of the Laboratories, King's College Hospital, a post he had to relinquish some two years ago on account of ill-health.

Emery was the author of "Clinical Pathology and Hæmatology," which passed through several editions and contains many practical hints, the outcome of his wide experience, and of "Immunity and Specific Therapy," which at the time of publication in 1909 presented an excellent critical survey of the extensive literature on these subjects. He was keenly interested in the problem of cancer, and a supporter of the parasitic hypothesis of the causation of this malady, arguments in favour of which are clearly set forth in another small book, "The Formation of Tumours." He published papers on the opsonic index and Wassermann reaction, and devised a simple method of complement fixation for the diagnosis of tuberculosis. He also contributed articles to Cheyne and Burghard's "Surgical Treatment," and Rose and Carless's "Surgery."

Emery was a bacteriologist and serologist of the first rank, and in later days a competent morbid histologist. Throughout his career he was overburdened with routine work; with more opportunity, it can scarcely be doubted his output of research work would have been larger. R. T. H.

Miss A. C. Breton.

We regret to record the death on June 15, at Barbados, of Miss Adela C. Breton at the age of seventy-three.

For more than thirty years Miss Breton travelled extensively and studied in many parts of the world, and her ready pen and keen powers of observation made her letters a delight to her friends. She had considerable talent as an artist, and utilised this gift to advantage in the pursuit of her archæological investigations. In Japan, for example, she made a very thorough study of the temples in a series of large water-colour drawings. Her name, however, will best be remembered in connexion with her expeditions to Mexico—which she visited thirteen times—and other parts of Central America, for the purpose of studying the antiquities of that region. In her travels in Mexico in the early 'nineties she rode on horseback, accompanied by one Indian only, a feat which in those days required both courage and much power of endurance. At the suggestion of Mr. A. P. Maudslay, she undertook to copy in water-colour the mural paintings of Chichen Itza in Yucatan, and produced a remarkable series of records of great beauty and high scientific value, unfortunately still unpublished. Miss Breton was also responsible for the copy of the pre-Columbian map of Mexico City, preserved in the National Museum of Mexico, and of the map of the Valley of Mexico, by Alonzo de Santa Cruz, in the University of Uppsala, which were published in Mr. Maudslay's translation of the "Conquest of Spain," by Bernal Diaz de Castillo. Of the former, Mr. Maudslay says it "needed long familiarity with Mexican picture-writing and topography to accomplish so successfully."

Miss Breton's great accuracy and industry served her and her readers well in the many papers on American archæology and other subjects which she contributed to scientific journals. She was a regular attendant at the meetings of the International Congress of Americanists, and was to a very large extent responsible for the organisation of the meeting held in London in 1912.

We regret to announce the following deaths:

Sir James Reid, Bt., Physician in Ordinary to Queen Victoria, King Edward, and King George, on June 28, aged seventy-three.

Sir Benjamin Simpson, formerly Sanitary Commissioner and Surgeon-General with the Government of India, on June 27, aged ninety-two.

Mr. S. S. Hough, F.R.S., H.M. Astronomer at the Cape of Good Hope, on July 8, aged fifty-three.

Current Topics and Events.

WE print as a supplement to this issue a discourse on muscular work by Prof. A. V. Hill, who will shortly be added to the physiological strength of University College, London. In it Prof. Hill shows how the original work of Fletcher and Hopkins on the production of lactic acid in muscles, the quantitative relationships between glycogen and lactic acid established by Meyerhof, and Prof. Hill's own elegant measurements of heat production, can now be added together into a coherent account of muscular contraction. The actual process which produces the mechanical energy is an explosive decomposition of glycogen into lactic acid, and the mechanism by which shortening of the muscle is caused—though this is of course speculative—is the neutralisation of this acid by bases; these are detached from their combination with proteids, which thereby lose their electrical charges and rearrange themselves in space. This part of the process is anaerobic, and the oxygen which is such a paramount necessity for the achievement of muscular work is needed not for the contraction but for the process of recovery. In this a portion of the lactic acid is oxidised, and provides the energy for the reconstitution of the bulk of the acid to glycogen. It thus becomes clear how it is possible for a man to do for short periods muscular work of a severity which requires sooner or later much more oxygen than he can possibly obtain through his lungs while the work is going on. Hence a man can for a short time run into debt for oxygen and obtain what he needs after the work is finished. For exercise of longer duration this shortage of oxygen cannot be progressively increased, and a man's capacity for it will depend mainly on his capacity for taking in oxygen and circulating it quickly to the tissues. Prof. Hill shows how well the actual record performances for flat racing over various distances fit in with the theoretical considerations. Athletic skill is also determined largely by dexterity in the economical performance of muscular work.

AT the meeting of the Council of the Royal Society on July 5, it was decided to use the larger part of the income arising from Sir Alfred Yarrow's gift of 100,000*l.* for the endowment of research, which was announced in February last, in the direct endowment of research by men who have already proved that they possess ability of the highest type for independent research. To this end a number of professorships will be founded, of type similar to the Foulerton professorships which were founded by the Society in 1922 for research in medicine. The professors will be expected to devote their whole time to scientific research, except that they may give a limited course of instruction in the subjects of their research to advanced students. There is at present a tendency to regard scientific research as a secondary occupation for men whose primary occupation is the teaching of students. The intention of the Royal Society in founding these professorships is to promote the recognition of research as a definite profession.

THE Royal Asiatic Society will celebrate its centenary during the four days, Tuesday to Friday, July 17-20, and the proceedings will be initiated by a reception of the delegates from other societies and bodies at the Royal Society's Rooms, Burlington House, at 10.30 A.M. on Tuesday, when H.R.H. the Prince of Wales has graciously consented to be present. This will be followed by a luncheon given by the Government to the delegates at Claridge's Hotel, and at 3.15 the delegates will meet their sectional chairmen at the Royal Asiatic Society's House, 74 Grosvenor Street, for an important part of the proceedings will be the reading of papers. For this purpose, the whole field of the Society's investigations has been divided into four sections: (1) the Ancient Far East (China and Japan); (2) the Ancient East (Babylonia, Assyria, Egypt, Palestine, etc.); (3) India (including Persia and Ceylon); and (4) Islam. On Wednesday, the morning sessions will be devoted to papers and discussions thereon; in the afternoon a visit will be paid to the School of Oriental Studies in Finsbury Circus, and the Lord Mayor has kindly promised to hold a reception at the Mansion House at 4 o'clock. Thursday and Friday mornings will be occupied by sectional meetings and papers, but the afternoons will be left free to permit the delegates and other associates to make personal arrangements as they may desire, taking advantage of their visit to London. The proceedings will close with a banquet at the Hotel Cecil at 7.30 P.M on Friday. Foreign visitors may enrol themselves on Monday, July 16, at the Society's House, and on Tuesday at the Royal Society's Rooms. Meanwhile any further information may be obtained from the Society's House.

THE list of honours recently issued contains the names of the following men distinguished for their scientific work or associations:— *Baronet*: Sir Anthony A. Bowlby, president of the Royal College of Surgeons. *Knights*: Dr. G. F. Blacker, dean of University College Hospital Medical School; and Prof. W. M. Flinders Petrie, Edwards professor of Egyptology, University College, London. *C.B.*: Mr. R. J. Thompson, assistant secretary, Ministry of Agriculture.

DR. T. ROYDS has been appointed director of the Kodaikanal and Madras Observatories in succession to Mr. J. Evershed, who retired on February 25 last.

SIR STEWART STOCKMAN, Chief Veterinary Officer and Director of Veterinary Research to the Ministry of Agriculture and Fisheries, has been elected president of the Royal College of Veterinary Surgeons.

AT the Cambridge meeting of the Society of Chemical Industry the following officers were elected for the year 1923–24:—*President*: Dr. E. F. Armstrong. *Vice-Presidents*: Dr. T. H. Butler, Mr. F. H. Carr, Prof. G. G. Henderson, Mr. E. Mond. *Ordinary Members of Council*: Prof. P. P. Bedson, Dr. R. T. Colgate, Prof. A. R. Ling, Dr. J. Reilly.

The Report of the Norwich Castle Museum Committee for 1922 gives a picture of the beautiful fifteenth to seventeenth century house known as Strangers' Hall. For many years Mr. Leonard G. Bolingbroke has been filling this with examples of English furniture and domestic appliances, as well as with many relics directly connected with the history of Norwich. He has now generously presented the freehold of the building and his collections to the city, and there was a ceremonial opening on July 4 by the Lord Mayor of Norwich.

Applications are invited for the post of Superintending Testing Officer under the Mines Department of the Government. The person appointed will superintend the testing work at the Mines Department Experimental Station in regard to safety lamps, electrical apparatus, etc., and the work of analysing samples of mine dust and mine air. Applications, accompanied by copies of two recent testimonials, should be sent by, at latest, July 21 to the Under-Secretary for Mines, Mines Department, Dean Stanley Street, S.W.1.

The summer conversazione of the Natural History Museum Staff Association was held in the Board Room on July 4, and was attended by about sixty members of the Staff and visitors. The specimens exhibited were mainly devoted to the exposition of symbiosis, but some dealt with the recent eruption of Mt. Etna, and a demonstration was given of crystals used in wireless telephony. Messrs. W. Watson and Sons, Ltd., showed their latest forms of microscopes and other optical apparatus.

The Belfast Naturalists' Field Club has issued the programme of its sixty-first session, 1923-24, and is to be warmly congratulated on its vitality through the years of Continental warfare and the still more trying years of civil disorder that ensued. Under the presidency of Mr. J. A. S. Stendall, a varied series of excursions has been arranged, mostly within the county of Antrim, which covers so wide a field of botanical and geological interest. One of the most ambitious of these outings, to the majestic and rarely visited volcanic neck of Slemish, took place on June 16. We are glad to note that Mr. R. J. Welch, on whom the Queen's University of Belfast has recently conferred the honorary degree of M.Sc., remains one of the most active promoters of the educational aspects of the Club, and that he is devoting especial attention to the development of the junior branch.

The Minister of Health has appointed the following committee to inquire into the use of preservatives and colouring matters in food: Sir H. C. Monro (chairman), Prof. W. E. Dixon, Sir A. D. Hall, Dr. J. M. Hamill, Mr. O. Hehner, Prof. F. Gowland Hopkins, Dr. G. R. Leighton, Dr. A. P. Luff, Dr. C. Porter, and Mr. G. Stubbs. The committee is to report: "(1) Whether the use of such materials or any of them for the preservation and colouring of food is injurious to health; and, if so, in what quantities does their use become injurious. (2) Whether it should be required that the presence of such materials and the quantities present in food offered or exposed for sale should be declared." The secretary of the committee is Mr. A. M. Legge, of the Ministry of Health, Whitehall, S.W., to whom all communications should be addressed.

The annual meeting of the Chaldæan Society was held at the rooms of the Royal Astronomical Society on Wednesday, July 4. In the absence of the president, the chair was taken by the treasurer, Dr. J. K. Fotheringham, of the University Observatory at Oxford. Reports of work from various local centres were presented. That from Ipswich was considered a specially successful and encouraging record of the season's work. It was reported that the Chaldæan Expedition to Wallal in Australia for the observation of the solar eclipse of 1922 had been completely successful,—being the only expedition sent from England that had met with success. Mr. Clark-Maxwell had now returned, but Mr. Hargreaves was going on to Mexico for observation of the eclipse this year, where Mr. Philip Myring intended to join him. The editor of the *Chaldæan* reported a growing appreciation in library and scientific circles, and expressed his thanks to a number of distinguished astronomers for the support they had given him. He would continue to pay special attention to the needs of amateurs and beginners. The following officers were re-elected for the ensuing twelve months: *President*, Mr. J. Hargreaves; *Treasurer*, Dr. J. K. Fotheringham; *Secretary*, Mr. E. W. Foster; *Librarian*, Mr. G. S. Clark-Maxwell; and editor of the *Chaldæan*, the Rev. D. R. Fotheringham.

Attention may be directed to the following reports which have been recently received: A. E. Verrill (Canadian Arctic Expedition Reports, vol. viii.) describes the Alcyonaria collected by the expedition and gives a revision of a number of other Canadian genera and species, and describes the Actiniaria, adding notes on interesting species from Hudson Bay and other Canadian localities. Both these reports are excellently illustrated. F. Johansen (in vol. vii.) contributes an account of the biology of the Crustacea found in some of the Arctic lagoons, lakes, and ponds, and a detailed report on the Euphyllopoda of the American Arctic.

We have received the fifth volume (1922) of Experimental Researches and Reports, published by the Department of Glass Technology of the University of Sheffield, and collected from the Journal of the Society of Glass Technology. These papers have been mentioned in Nature as they appeared. There are papers on the action of chemical reagents on glassware, the determination of the durability of glass, as well as on more technical matters. The presidential address by Prof. Turner dealt with "The British Glass Industry, its Development and Outlook," and contains some interesting historical material. One "outlook" is interesting to the layman: "It would not be difficult, if the glass manufacturer set about it in earnest, to write up a fearful account of the many-headed hydra, reptiles, and bugs that infect food not protected by glass, and, on the strength of the fright so administered, soon work up a trade the extent of which might be enormous."

THE new catalogue of second-hand books (No. 225) of Messrs. W. Heffer and Sons, Ltd., Cambridge, is of a miscellaneous character, but it contains many works likely to be of interest to readers of NATURE, *e.g.* those dealing with folk-lore, occult literature, and Egyptology. A useful section is that devoted to foreign literature.

MESSRS. NEGRETTI AND ZAMBRA, of 36 Holborn Viaduct, London, E.C.1, have recently sent us a spirit thermometer of a useful pattern for indoor use. It is mounted on a metal frame, the graduations in degrees Fahrenheit being black on a white ground. The bulb is protected by a strong guard made as a part of the frame.

MR. VALENTINE DAVIS, of Noddfa, Wistaston, Crewe, is organising a holiday course in Chamonix, on August 17-September 1. It is proposed to make excursions to various glaciers and passes, using Chamonix as headquarters, and the flora of the district, the geology of Mont Blanc, and similar field-studies will be made. Particulars can be obtained from Mr. Davis.

MESSRS. GEORGE ROUTLEDGE AND SONS, LTD., have ready for publication part 3 of the third edition of Sonnenschein's "The Best Books: a Classified Bibliography." It deals with history and biography, and historical collaterals, and contains particulars of some 24,000 books. The fourth and concluding part will, it is hoped, be published at the close of the present year. It will deal with the sciences, industries, arts, literature, and philology, and contain complete indexes of authors and subjects.

DR. W. BROWN is bringing out through the University of London Press, Ltd., under the title of "Talks on Psychotherapy," the course of lectures recently delivered by him at King's College, London. It will deal with the subjects of functional nerve disease, psycho-analysis, abreaction and transference, the libido theory and melancholia, auto-suggestion, etc. Other books to be published by the same house are three by Dr. Cyril Burt on "The Sub-Normal School Child," entitled respectively "The Young Delinquent," "The Backward and Defective Child," and "The Unstable and Neurotic."

Our Astronomical Column.

CORRECTION TO THE LONGITUDE OF BORDEAUX OBSERVATORY.—A note in the *Journal des Observateurs* for June, by J. Trousset and L. Gramont, contains the rather surprising announcement that the accepted value of the longitude of the Bordeaux Observatory is a second of time in error. This was based on an elaborate determination, made in 1881 by MM. Rayet and Salats, both observers and instruments being interchanged. The amount is altogether beyond the probable error of the determination, and presumably arose from some systematic error in marking the seconds on the chronograph tapes, or some similar cause.

The error was detected by the reception of the Paris wireless signals at Bordeaux, and a new determination of the longitude was then made by means of these signals. The resulting value of the longitude of Bordeaux west of Greenwich was $2^{m}\ 6{\cdot}564^{s}$, the mean error being $0{\cdot}023^{s}$. The old value, printed in the Nautical Almanac, is $2^{m}\ 5{\cdot}51^{s}$.

The new determination, though only just published, was made in April and May 1921; presumably it was in use throughout 1922 in the wireless time signals sent out from Bordeaux and received at Greenwich. The mean difference between the Greenwich times of receipt of the Paris and Bordeaux signals was only $0{\cdot}04^{s}$.

SILICON LINES IN B-TYPE STARS.—In the determination of the radial velocities of B-type stars, the wave-lengths of the lines of silicon are constantly being used, but the values employed have not been referred to modern standards of wave-lengths. The lines in the spectrum of silicon alter as the temperature is increased and the enhanced or ionised lines occur as doublets and triplets alternately and are known as Si II, Si III, and Si IV as first differentiated by Sir Norman Lockyer. A new determination of the wave-lengths of those lines has just been completed by Mr. H. Barrell in the laboratory of Prof. Fowler (Mon. Not. R.A.S., vol. 83, p. 322), and he gives both the adopted values in International Units and in Rowland's scale. While the instrument employed in the determination was not the one that was most desired, since the latter is still in detention in Russia, that employed gives, as is stated, "the desired redeterminations with every possible precaution to ensure a high degree of accuracy." As the silicon wave-lengths are in very general use it is important that these new values should be widely known; they are briefly summarised below:

Group of lines.	Adopted values in I.A.	Probable errors.	Wave-lengths in Rowland's Scale.
Si II . . .	3856·021	±0·001	3856·165
	3862·592	0·002	3862·737
	4128·053	0·001	4128·207
	4130·884	0·001	4131·038
Si III . . .	4552·611	0·002	4552·782
	4567·824	0·002	4567·995
	4574·737	0·002	4574·908
SI IV . . .	4088·863	0·001	4089·016
	4116·104	0·002	4116·257

A VARIABLE OF VERY SHORT PERIOD.—Mr. F. C. Jordan, of Alleghany Observatory, contributes a note to *Astron. Journ.*, No. 821, on a star of magnitude about $11\frac{1}{2}$, on the same plate with the Cepheid variable S Comae; the period of light-variation is only $2^{h}\ 50{\cdot}8^{m}$, the light-range being 0·73 mag. The light-curve is very pointed at minimum, there being no stationary interval. There is none at maximum either, but the curve is here rounded, not pointed. From comparison with some similar curves it is thought likely that the star is of the Beta-Lyræ type rather than the Algol type; in this case the period will have to be doubled. The two portions of the curve are so alike that in this case the two stars must be very similar in size and brightness. It is feared that the star is too faint to decide the matter by spectroscopic determinations of the radial velocity.

The approximate position of the star for the equinox of 1900 is R.A. $12^{h}\ 28^{m}\ 4^{s}$, N. Decl. 27° 16·1′.

Research Items.

Cancer in the United States.—The incidence of cancer in the United States is discussed by Dr. F. Hoffman in an article in the *World's Health* for May, p. 18. In the general registration area, the cancer death-rate has increased from 74·4 in 1911 to 83·4 in 1920 per 100,000 population, but in some of the individual States is much higher, and, making all allowances, the conclusion is that cancer is seriously on the increase. A dangerous phase of the cancer problem is that alleged cancer cures are gaining in popularity, with results disastrous in the end. Dr. Hoffman states that having personally investigated the incidence of cancer among Indian tribes in the south-west and in Bolivia, he is satisfied that malignant disease in any form, and particularly cancer of the breast, is extremely rare.

The Teeth of Piltdown Man.—In the *American Journal of Physical Anthropology* (vol. vi., April-June), Dr. Aleš. Hrdlička publishes an important contribution to the study of the phylogeny of man in a paper on the dimensions of the first and second molars, and their bearing on the Piltdown jaw. Dr. Hrdlička has subjected to a detailed analysis the recorded measurements of these two molars in man, and has made a careful examination of the material in the U.S. National Museum. As a result, his conclusions are that the Piltdown molars are longer and have a lower index than any group of modern men; as compared with early man they exceed in length all prehistoric molars except one or two first molars from Krapina, and, with one exception, present the lowest breadth-index; in breadth they are ordinarily human. When compared with the apes it is clear that they do not belong to this group, though nearest in proportion to the gorilla. Of the fossil apes, the teeth most closely resembling the Piltdown teeth are those of *Dryopithecus rhenanus*, Pohlig, of the Bohnerz Alb. Dr. Hrdlička's general conclusion is that the Piltdown teeth, primitive as they are, belong to very early man or to his very near precursor, while he suggests that the resemblance to the late Miocene or early Pliocene human-like teeth of the Bohnerz Alb. may legitimately raise the question whether man may not have evolved altogether in Western Europe.

Human Sacrifice as a Rain Charm in Northern Rhodesia.—In January last a report appeared in the *Times* which stated that eighty natives had been arrested in Rhodesia for complicity in a case of human sacrifice due to witchcraft. This report was of peculiar interest in view of the fact that the natives of this region, which lies about forty-five miles beyond Mount Darwin, just on the boundary of Portuguese territory, are noted for their addiction to witchcraft in a form which presents some remarkable parallels to the traditional rites and practices of European witches. From the evidence given at the trial, of which an account is given in the *Times* of June 26, it would appear that in this instance it was not a case of witchcraft in the generally accepted sense. The sacrifice was offered by the Mtawara tribe to propitiate Mwari, the Great Spirit of the tribe, and thus bring to an end a drought which threatened the tribe with disaster. Mwari has two wives. One came some generations ago from a branch of the tribe living in what is now Portuguese territory and was domiciled within a circle of trees, presumably a sacred grove. This wife, Mashongavudzi, is an old woman, past child-bearing, whose husband is dead. At her death her place is taken by another old woman who assumes the same name. The second wife, Nechiskwa, is chosen from the family of Gosa, the chief of the branch of the tribe in Portuguese territory, when a child—the present holder of the office is about nine years old—and must remain a virgin throughout her life. She is the Rain Goddess. When there is a drought Gosa sends an offering of *limbo* (coloured cotton print) to the Mwari, which is placed near the throne of the Rain Goddess. If rain fails to follow, Mwari is angry because some one has seduced his wife. The only remedy is that the culprit should be sacrificed by fire. In this case suspicion fell on a son of the chief who is in charge of the wives of Mwari—an office which has descended to him from his ancestors. The accused man was duly offered up as a sacrifice by burning and, curiously enough, rain followed in twenty-four hours.

Kata-thermometer Studies.—Dr. Leonard Hill's campaign against the stagnant, warm atmospheres which are encouraged by many of the modern plans of warming and ventilating buildings is steadily gaining the success it deserves. Cool moving air and local radiant heat mean a cool head and warm feet, which is the ideal state for human comfort and efficiency. The stimulating qualities of an atmosphere depend on its temperature, humidity, and movement, and in the kata-thermometer Dr. Hill introduced an instrument which gives directly a measure of the cooling and evaporative powers of the air; *i.e.* the properties which through their action on the skin determine the pleasantness for man. "The Kata-thermometer in studies of body heat and efficiency" (Medical Research Council Special Report Series, No. 73, 1923) gives a mass of data collected by Dr. Hill, Dr. H. M. Vernon, and others, under a variety of conditions ranging from boot and shoe factories to imitations of shipwrecked sailors in the wind tunnel at Hampstead. There is also a discussion of the theory and practice of the instrument and a description of a recording apparatus designed by Dr. E. H. J. Schuster. The section on the relation of general metabolism to kata-thermometer readings raises a question of considerable importance to which no answer seems to be yet available. Atmospheres which are "good" by Dr. Hill's standard increase metabolism, and more food is needed and desired. Riding on the top of a bus, for example, instead of inside, means, as he points out, a greater expenditure on food. It is also generally agreed that it promotes general healthiness and vigour. But why is it that a high rate of metabolism is better for the body than a low rate? The effect may be essentially psychological, but the point requires discussion. The whole report will well repay detailed examination.

Tsetse Flies.—The April issue of the *Bulletin of Entomological Research* contains a report of Drs. W. B. Johnson and L. Lloyd on tsetse fly investigation in the northern provinces of Nigeria. The authors bring forward evidence showing that sleeping sickness can appear and become epidemic in localities where the only tsetse carrier present is the species *Glossina tachinoides*, and it is at least probable that this insect is responsible for the disease in certain localities where it abounds and the usual carrier *G. palpalis* is rare, or wanting. Both *G. palpalis* and *G. tachinoides* suck the blood to a considerable extent of the non-mammalian fauna—probably that of reptiles. The two species can thrive where the wild fauna is reduced to its possible minimum, and *G. tachinoides* where man is almost the only available host. The authors anticipate that

the work of controlling the latter species will resolve itself into a study of the problems of clearing the jungle, since curtailment of its food supply does not appear likely to be effective. In the same journal Dr. G. H. D. Carpenter contributes an article on the use of artificial breeding places as a means of control of *Glossina palpalis*. The breeding places took the form of low thatched sloping roofs erected over suitable loose soil in localities where the fly is known to abound. The insects used the shelters as convenient places for depositing their larvæ, which very soon afterwards pupate. The result of the catches from these shelters showed that in some cases they were superior to the natural places selected by the flies. It is concluded that, although the method affords a ready means of collecting material for laboratory investigations, it is ineffective as a means of destroying the Glossina without other measures. After very nearly a year the number of pupæ deposited showed no appreciable diminution.

BRITTLE-STARS OF THE PHILIPPINES.—The Smithsonian Institution has recently published, as volume 5 of its Bulletin 100, a memoir by Prof. R. Koehler on the Ophiurans collected by the *Albatross* in Philippine and Samoan waters. Out of the 227 species discussed, 68 are new, and these include examples of 5 new genera. Since many of the other species had previously been inadequately described, they too now receive full description and illustration. The illustrations are entirely photographic, a method which Prof. Koehler claims as the only satisfactory one for the systematist. When the photographs are as good and as well-reproduced as are most of Prof. Koehler's, and when, as here, enlarged photographs of details are provided, then, on the whole, we agree with this claim. But even when all the conditions are fulfilled, explanatory diagrams are a most welcome addition. The classification adopted is that of Matsumoto, with a few modifications of detail (but why Lœmophiurida instead of Læmophiurida ?). The work has been translated from the French by Mr. Austin H. Clark into clear and easy English: we would observe only that the English for "Lyon" is "Lyons."

FOSSIL BISON FROM CENTRAL MINNESOTA.—From a peat swamp overlying the iron ore at the Sagamore Iron Mine, Riverton, Minnesota, bones of *Bison occidentalis* have been recovered which form the subject of a paper by Mr. O. P. Hay (Proc. U.S. Nat. Mus., vol. lxiii., art. 5). The bones were at or near the bottom of the peat, which overlies drift beds determined to be of about mid-Wisconsin age, so that *Bison occidentalis* lived in Minnesota until the middle of the last glacial stage, but how much longer cannot now be determined. Whether the presence of the remains of *Bison bison*, that also occurred in the peat, indicates that the two animals were at one time contemporaneous in that region, or whether the existing buffalo arrived there after the other had become extinct, is uncertain.

GIANT HORNLESS RHINOCEROS FROM MONGOLIA.—In 1913 Mr. Forster Cooper described under the name of *Thaumastotherium* (afterwards altered to *Baluchitherium*) *osborni* a huge rhinoceros-like animal of which he had unearthed the remains on his expedition to Baluchistan. A second species, *B. grangeri*, was discovered at Loh, central Mongolia, in 1922 by the third Asiatic expedition of the American Museum of Natural History. This new species is now described by Prof. H. F. Osborn (Amer. Mus. Novitates, No. 78), who further makes the genus the type of a new subfamily—Baluchitherinæ. The author considers that the Baluchitheres will prove to be unique, large animals of the age (Upper Oligocene, or Miocene) in which their remains occur, and that they were typical browsers feeding on the branches of trees as do elephants and giraffes. When the neck was elevated and stretched the animal would have attained a height of about fifteen, or possibly sixteen feet. A restoration is given which shows that at the shoulder Baluchitherium was twice the height of the Indian rhinoceros with which it is compared.

LATE MESOZOIC BATHOLITES AND ORE-DEPOSITS IN JAPAN.—While the attention of geologists is being justly redirected to the major "revolutions of the globe," and to the relative rapidity of their culminating episodes, it is well to note the evidence of intervening epochs of unrest. The "Laramide revolution" of Schuchert, which is held by many to have heralded the great days of Andean crumpling, can be traced back to "epeirogenetic" movements in the Rocky Mountain area in late Cretaceous times; and these are now seen to have had "orogenetic" analogues on the other side of the Pacific. Here we may observe, as a corrective of too rigid doctrine, that the folding took place on the eastern side of a continental mass. Prof. T. Kato of Tokyo (*Japanese Journ. of Geol. and Geogr.*, vol. i. p. 77, 1922) describes the intrusion of huge batholites of quartz-diorite and granite into Jurassic strata in central Japan, and he traces the famous copper-ores of the Yamahara district in the province of Mimasaka to a late Mesozoic epoch of unrest. The first result of the igneous intrusions was the contact-metamorphism of the sedimentary series. Then, at a temperature a little below the critical point of water, tourmaline and fluorspar were produced; and the sulphide ores, including copper and iron pyrites, pyrrhotine, and zinc-blende, followed, and permeated the invaded areas. Veins of quartz and calcite mark the final stage. A neat diagram on p. 99 shows the succession of igneous types, closing with rhyolites that reached the surface. Volcanic manifestations continued into Cainozoic times; but the epoch of maximum disturbance is assigned to the close of the Mesozoic era. The paper is written in English and is very well illustrated by photographs.

PETROGRAPHY OF DRILL-CUTTINGS FROM OIL-WELLS.—One of the first attempts in the United States towards the intensive petrographic examination of rock-samples obtained while drilling oil-wells, is described in an advance chapter (H) of bulletin 786 of the United States Geological Survey, by Messrs. J. Gilluly and K. C. Heald. Their report deals with the stratigraphy of the El Dorado oilfield, Arkansas. Petrographic methods of correlation of strata have come into prominence in England and in several of the British-owned oilfields within the last seven or eight years, but, so far as we know, little attention has been paid by oil-geologists in the United States to this phase of exploratory work. The authors rely entirely on the lithological characters of the samples, on their differentiation according to the amounts of sand, clay, and lime present, while limonite, lignite, or glauconite are specifically indicated where sufficiently obvious. Any fossils found are also carefully studied in conjunction with this petrographic investigation, a collaboration to be highly commended. It is, however, unfortunate that the authors did not go a great deal further with their petrographic work; the "heavy" detrital minerals (*i.e.* those having a specific gravity greater than 2·8) furnished by the samples would have formed a much more definite basis of comparison

and discrimination between the beds involved, and zoning would have been facilitated accordingly. Authigenous constituents of sediments vary qualitatively and quantitatively within small limits far more than the more stable detrital grains do, and for this, if for no other reason, the study of the "heavy" minerals is always desirable. Notwithstanding the neglect of these constituents, however, the authors have grouped their samples into ten zones, comprising parts of the Tertiary and Upper Cretaceous formations in the district; such zones are of incalculable value to the drillers and others engaged in exploring the field, but it would be interesting to know how far such zones were confirmed or contradicted by similar work based on 'heavy" mineral assemblages.

BRACHYSTEGIA, A TROPICAL SOURCE OF FIBRE AND TIMBER.—Messrs. J. Burtt Davy and J. Hutchinson describe fifty-four species of Brachystegia in the *Kew Bulletin*, No. 4, 1923. This genus is confined to equatorial Africa, and is so dominant in the vast forest area extending between the Limpopo Zambesi watershed and the Katanga Plateau at the head waters of the Congo River, and from Nyasaland to the Angola Highlands, that this plant formation might well be termed "Brachystegia Forest." All species are trees with fibrous bark, sometimes containing tannin, and the natives of Central Africa use this bark for an extraordinary variety of purposes. Brachystegia bark cloth is used for making grain sacks and game nets, the fibres of some species being used for the manufacture of cord and rope of all sizes and for all purposes. Before the widespread introduction of cotton goods, the principal clothing of the native was bark cloth made of fibrous sheets beaten out of the bark of several species of Brachystegia. The timber of some species is described as hard and durable and suitable for building purposes, that of others as too soft. Undoubtedly both fibrous bark and timber may have many industrial applications, but the first step towards economic development is a clear idea of the different species of the trees and their different possibilities. To this end the taxonomic study in the *Kew Bulletin* should have great value, as one of the authors has studied the plants in their native habitat and a first attempt is made to indicate what different species are probably intended by the vernacular names used by the natives.

LIBERATION OF PRUSSIC ACID FROM THE PLANT LEAF.—The highly toxic properties of hydrocyanic acid have caused the accumulation of a considerable literature upon the subject of its production in plant tissues from cyanogenetic glucosides under various conditions. The problem is obviously not simple, and, as occasional cases of stock poisoning are traced to this source, its study has economic as well as scientific interest. F. J. Warth has recently studied the liberation of prussic acid from the tissues of the Burma bean (*Phaseolus lunatus*), and supplies some very interesting data in the Memoirs of the Department of Agriculture in India (Chemical Series), vol. vii. No. 1. He points out that the amount of prussic acid produced differs materially according to whether the leaves are dried rapidly in the sun or slowly in the shade. In the sun-dried leaf, hydrolysis takes place with evolution of prussic acid, and if the dried leaf be plunged into boiling water further large amounts of the acid are given off; this effect is not produced with the fresh leaf or slowly-dried leaf. It appears that in the slowly dried leaf the enzymic balance approximates to that in the normal leaf, and in this balanced system prussic acid appears to be further changed as rapidly as it is released by enzymic hydrolysis of the glucoside; indeed, both fresh leaf and slowly dried leaf show some capacity to cause the disappearance of additional acid, if added to water containing the crushed or powdered leaf material.

SHORT-WAVE DIRECTIVE RADIO TRANSMISSION.—Franklin and Marconi have shown that when the wave-lengths used in radio transmission are less than 20 metres it is not difficult to get directive transmission. For transmitting news and music, broadcast directive transmission is not wanted, but for broadcast reception it can be usefully employed, as by its means interference disturbances may be reduced to a minimum. Its principal use is in connexion with point-to-point communication, *i.e.* direct communication from one transmitting to one receiving station. In particular it will be useful in the new methods adopted of transmitting photographs by radio and for the remote control of mechanisms. In paper No. 469 published by the Bureau of Standards, F. W. Dunmore and F. H. Engel give the results of experiments with directive radio transmission on a wave-length of 10 metres. As a reflector they use a series of forty vertical parallel wires all of which lie on the surface of a parabolic cylinder. It is so mounted that it can be rotated about a vertical axis. The focal length of the parabolic section was made one-quarter of a wave-length, 2·5 m. (8 feet 2·4 inches). Each of the wires was tuned to 10 metres, and they were spaced 30·47 cm. apart. A 50-watt three-electrode valve of the coated filament type was used as a generator. Radiation characteristic curves are given from which it appears that at least 75 per cent. of the radiated power is confined to an angle of 40°. It was noticed that with this type of transmission the absorption by buildings and other metallic structures was very pronounced.

WEATHER AT EASTBOURNE IN 1922.—Eastbourne Borough Council has recently issued its annual report of the meteorological observations for the year 1922. The records have been kept continuously since 1887, a period of 36 years, so that valuable statistics are available as to the weather and climate of this much-favoured health resort. Observations are supplied to the Meteorological Office and are included in the Weekly, Monthly, and Annual Weather Reports, as well as in the Daily Report of Health Resorts. In addition to the observations at Eastbourne the report comprises similar results for other health resorts scattered over England, taken from the Meteorological Office returns, from which it can be seen that Eastbourne occupies a position with a fairly equable temperature, with a large amount of sunshine, and with a rainfall by no means excessive. The mean air temperature in 1922 ranged from 59·2° F. in August to 41·6° F. in January, and the mean for the year was 49·9° F. The duration of sunshine ranged from a mean of 10·40 hours per day in May to 1·76 hour per day in December, the mean for the year being 4·80 hours per day. The mean monthly rainfall for 1922 ranged from 4·31 in. for January to 0·61 in. for May; the total for the year was 28·10 in. The prevailing winds were from the west and north-west, though in most recent years the prevailing winds have been from between south-west and north-west. From this prevailing direction the air has to pass over the South Downs before reaching the town, and, mixing with the air over the sea, may often account for a fair amount of fog in the Channel, in the neighbourhood of the *Royal Sovereign* Lightship, and frequently may render the air somewhat humid over the land.

The International Air Congress, 1923.

THE second International Air Congress since the War was held in London on June 25-30. It was attended by about 600 members representing no less than 20 countries. The Duke of York was president of the Congress, and the Duke of Sutherland, Under-Secretary of State for Air, chairman of the committee. The Congress was opened on June 25 with an address from the Prince of Wales. During the week the meetings for papers and discussion were held in the buildings of the Institution of Civil Engineers. Three days were devoted to these, while two were utilised in visits to works and places of interest to the members. Thus on Tuesday a large party visited the Royal Aircraft establishment at Farnborough, while on Thursday the National Physical Laboratory attracted many interested members.

In addition to the official gatherings, receptions were given by the Lord Mayor and the Duchess of Sutherland, while on Friday afternoon the Secretary of State for Air and Lady Maude Hoare entertained the Congress at a garden party at which the Duke and Duchess of York were present. Saturday was devoted to a final meeting, with the Secretary of State for Air in the chair, at which a number of resolutions were passed. The Congress then adjourned to Hendon to view the Royal Air Force Pageant, and the week closed with a successful banquet, with the Duke of Sutherland in the chair. Colonel Lockwood Marsh, secretary of the Royal Aeronautical Society, was secretary of the Congress, and received the very cordial thanks of the Congress for the admirable arrangements by which its success was secured.

For the papers and discussions the Congress divided into four groups, as follows:—(A) Aerodynamics, construction and research; (B) power plants—fuels, lubrication, airscrews, etc.; (C) air transport and navigation; and (D) airships.

In each of these a number of interesting and important papers were read; the papers, with the discussions, will be issued shortly in book form. Readers of NATURE will probably find most to interest them in Group (A).

Some fifty years ago Lord Rayleigh directed attention to the effect of circulation of air round a cut tennis ball, having spin, as well as forward velocity, in modifying the motion of the ball and causing it to follow a curved path. In his well-known book on aerodynamics, Lanchester applied the same idea to account for the lift on an aeroplane wing, and described the manner in which the vortex system set up round the wing was completed by two series of trailing vortices shed off from each wing tip. These carry away part of the energy and thus give rise to a portion of the drag—known now as the induced drag—which resists the motion of the aeroplane.

Lanchester's work was descriptive and its importance was scarcely recognised; numerical results, figures, and mathematical calculations were needed before its great value was grasped. We now see that it contains the solution of the problem; the intuitive eye of the genius forestalled the slower methods of the mathematician, though laborious calculations and the work of expert draughtsmen and experimenters were necessary to establish its fundamental truths. Several of the most important papers in Section A were devoted to this subject.

Starting from the known solutions of the flow round an infinite cylinder moving uniformly in a fluid in which there is circulation round the cylinder, Joukowsky and Kutta transformed the motion into one about a long cylindrical body having a section resembling that of an aeroplane wing, but with an infinitely thin trailing edge. They obtained an expression connecting the lift on such a wing supposed to be of infinite aspect ratio—*i.e.* infinitely long in comparison with its width in the direction of flow—with the circulation. The motion is thus two-dimensional in planes at right angles to the length of the wing.

One of the stream-lines near the tail leaves the wing at right angles to its upper surface, and unless this point coincides with the trailing edge the motion breaks down and the velocity becomes infinite. By adopting a suitable value for the circulation the stagnation point can be brought into close coincidence with the trailing edge, the motion becomes steady, and the lift can be determined; the value so found is, however, some 20 per cent. too great, and the theory does not account for the drag. There would be no resistance to the motion of such a wing.

Major Low, in one of the papers read to the Congress, gave an interesting account of a draughtsman's method of applying the Joukowsky theory to a wing of any form.

This simple two-dimensional theory was modified by Prandtl and his school. He assumes the wing to shed vortices all along its trailing edge from the centre outwards, forming a vortex sheet which at a little distance behind the aeroplane rolls up into a single long vortex trailing away from each wing tip in a direction opposite to that of motion, as in Lanchester's suggestions. Thus the circulation, and hence the lift, falls off as one passes outwards along the wing; and, assuming a law for its decrease, Prandtl obtains an expression for the lift on a wing of finite aspect ratio, and, by taking into account the effect of the trailing vortices, for the drag considered as due to the action between these and the wing vortex—the induced drag. This accounts for a large percentage of the observed drag. In England, Mr. Glauert has done much in connexion with this theory, which has been applied to the interference of the channel walls on a model under test, to the theory of the propeller leading to Froude's coefficient of 0·5 for the induced flow near the propeller, and to other problems. Mr. Glauert's paper gave an important résumé of the present position.

But there is a fundamental difficulty: the fluid is treated as inviscid, and in such a fluid the motion of a body will not set up vortices; the body will experience no drag. Air is viscous, and the value of the kinematic coefficient of viscosity has an important bearing in aerodynamics, while the shearing forces set up by the viscosity depend on the rate of change of velocity in the direction normal to the flow. Now, since the fluid, if viscous, is at rest relative to the body at all points of its surface, the rate of change of velocity, and therefore the viscous shear, will be greatest close to the surface. The Prandtl theory supposes that such viscous forces are sensible only throughout a very thin film surrounding the surface, which suffices to set up the circulation, and that outside this film the equations of an inviscid fluid may be used.

Prof. Bairstow in his paper, after a reference to his recent communication read before the Royal Society, suggested that an attempt to relate the circulation theory to the fundamental equations of motion, taking viscosity into account, would lead to a determination of the friction on the surface of the aerofoil, thus giving that part of the drag which is omitted from the Prandtl theory. Promising work on these

lines is in progress in the Aeronautical Department of the Imperial College, South Kensington, which is thus beginning its work as a centre of advanced research.

To turn to other parts of the discussions in Group (A), mention must be made of a most important paper by Mr. Handley Page on the slotted wing. The author gave the most recent details of his wind-channel tests on his device for enabling the pilot to increase effectively the lifting power of the wing. This enables him to land at a much lower speed than would be otherwise possible. Reference must be made to the paper for the figures; it must suffice to say that in the case of one section known as Airscrew 4 the maximum lifting coefficient was increased from 0·7 to 1·1, while for the well-known section R.A.F. 15 the increase was from 0·55 to 0·95. The meeting was pleased to hear from the representative of the Royal Air Force that the full-scale tests, so far as they had been completed, were successful.

Methods of measurement in experimental work were discussed in various papers. Col. Robert, of the Technical Aeronautical Service of France, gave a detailed account both of the precautions necessary to secure accuracy in the results and of the delicacy of the tests, thus confirming the experience of the workers at the National Physical Laboratory, Teddington. Our French colleagues are to be congratulated on the possession of the new air-channel which is now being installed. The channel is 3 metres, say 10 ft., in diameter, and the maximum air speed 30 metres, or about 100 ft. per second. The standardisation, or rather the intercomparison, of methods of research was discussed by Sir Richard Glazebrook in his paper dealing with the international tests now in progress. Mr. Southwell described the most recent apparatus at the National Physical Laboratory, and Mr. M'K. Wood dealt with the accuracy of model results and their comparison with full-scale work.

Among the other papers, one by Mr. Baumhauer, of the Dutch Institute for Aeronautics, on the methods of computing wing sections, met with general approval, while Mr. North's paper on the technical development of the aeroplane aroused much interest. It must suffice to mention them, together with the papers on stability by Mr. Barlow; on control at low speeds, by Mr. M'K. Wood; and on testing of strength, by Mr. Douglas. Another paper by Messrs. Baumhauer and Groning dealt with the vibrations of an aeroplane wing, a subject which is being investigated both at the National Physical Laboratory and at Farnborough.

It will be obvious from the above that those members of the Congress who attended Group (A) were kept fully occupied with interesting and important problems.

And now to conclude; limits of space forbid anything but the briefest reference to the other papers, not that they were less interesting or less important than those of Group A. There is no one better able to speak on airship travel than Major Scott, with his experience of two voyages across the Atlantic. Colonel Richmond is an authority on airship structure, while Signor Nobili has acquired a world-wide reputation from the success of the Italian ships. Some comparison of their performance with those of our own non-rigids would be interesting. Moreover, full-scale experimental work, if airships are to be constructed on a scientific basis, is still required, though our knowledge has been increased by recent American work.

Members attending Group B were interested in various papers connected with engines, such as Mr. Charlton's account of the crude oil engine, Wing-Commander Hyne's description of engine work at Farnborough, and the communications on lubrication by Dr. Stanton, Mr. Evans, and Mr. Hersey, while on Wednesday morning the discussion on air mails and the development of commercial aviation by General Williamson, Jonkherr van Hemstede, and Mr. Handley Page attracted a large and attentive audience to Group C. In every way the Congress proved a great success, and its members acclaimed Sir Samuel Hoare's toast at the concluding meeting, "To our next merry meeting, Brussels, 1925."

The National Physical Laboratory, Teddington.

ANNUAL VISITATION.

ON Tuesday, June 26, the General Board of the National Physical Laboratory made the annual visitation to the Laboratory. As is customary on this occasion, a number of members of scientific and technical societies and institutions, government departments, and industrial organisations were invited, and the Laboratory was open for inspection. The visitors were received in the new aerodynamics building by Sir Charles Sherrington, chairman of the Board, Sir Arthur Schuster, and the director of the Laboratory.

Since the last visitation the Laboratory has been somewhat extended, and Victoria House, acquired a few years ago to meet the anticipated increased demands of the work, has been converted for the use of the Physics Department. Most of the temperature work involving the testing and standardisation of mercury, resistance, and optical pyrometers is carried out here, in addition to the investigations of the newly created sound section. The Metallurgy Department has been provided with much-needed increased accommodation by the addition of a new story to the Wernher Building, in which a number of offices and small laboratories, as well as a special room for high temperature work, have been equipped.

A very large number of interesting exhibits were shown in the various departments. It is, however, impossible to do more than describe briefly a few of the more noteworthy, which show the wide range of phenomena, from the highly theoretical to the severely practical, which the Laboratory is called upon to investigate.

In the Aerodynamics Department the wind-tunnels were shown in operation. In the duplex wind-tunnel, which has a working portion 14 ft. wide, 7 ft. high, and 80 ft. long, two motors of 200 h.p. develop wind speeds up to about 110 ft. per sec. (75 miles per hour). A test on a Bristol Fighter aeroplane was demonstrated in which, on a model (¼ full size) having a motor-driven airscrew, an experimental investigation of the effect of slip-stream on the behaviour of the plane is being carried out. The "whirling arm," which is driven through a worm gear by a 12-h.p. motor giving speeds of advance up to 50 ft. per sec., was shown employed in the determination of the pressure distribution on ellipsoids travelling in circular paths. This has an important application in the deduction of the stresses imposed on the hull of an airship which is turning.

Another interesting exhibit showed an electrical method of determining the stream-lines of an inviscid fluid past an aerofoil of any given section. It can be shown theoretically that the equipotential lines of a system consisting of an insulated conductor between two charged parallel plates are identical in form with the stream-lines in a perfect fluid flowing

parallel to the plates past the same conductor. By the use of exploring electrodes connected to telephones through a three-valve audio-frequency amplifier, it is possible to determine positions of the electrodes which reduce the sound in the telephones to a minimum, and hence obtain the equipotential lines of the system, or the stream-lines for the case of fluid flow.

In the Engineering Department a new method of testing the efficiency of gear-boxes was shown in which the difference of the input and output powers is measured directly and not as a difference. The method consists of the observation of the torque produced as a consequence of the difference of the input and output powers when the gear-box was supported in a tilting frame. Apparatus was shown for the study of explosions in closed vessels. This has an important application in the design of internal combustion engines where it is desirable that the explosions should occur under the most favourable conditions of temperature and pressure of the mixture. This is, of course, largely influenced by the compression ratio, which is, however, limited in effect by detonation or "knocking" at high compression ratios.

In connexion with the experimental study of roads and road materials a new plant for the preparation of bituminous macadam was exhibited. The plant consists of two units, one for mixing sand, etc., at a temperature of 600° F., and the other for mixing the aggregate with bitumen. It is capable of mixing about six tons of road metal per hour. Other exhibits included apparatus for the investigation of fatigue under uniform bending moment, and its correlation with the microstructure of the material; the endurance of ball-bearings under axial loading; and the hardness of materials as tested by their ability to resist scratching by a diamond.

The main exhibit in the William Froude National Tank was the method of determination of the stresses liable to be set up in the rudder heads of ships when the rudder is altered in certain definite ways. The problem is one on which attention was focussed during the War, when even with vessels which were classed A1 at Lloyd's damage to stearing gear was of much more frequent occurrence than was anticipated. For this purpose a ship model capable of independent motion and external control was under observation from the travelling carriage of the tank, and the effect of putting the helm over at various rates and through different angles investigated. The experiments show that it is possible to add more than 50 per cent. to the strain on the rudder head by changing the helm too quickly.

Other exhibits included apparatus for determining the stresses on a rudder behind a fin plate with twin screws, and for the determination of the resistance, rise, and angle of seaplane models in motion.

In the Metrology Department standard weights were exhibited. In this connexion it is interesting to note the experiments of the Laboratory on a new material, stellite, as a substitute for platinum for standard weights. Stellite, which is an alloy of chromium, cobalt, and tungsten, is exceedingly hard, and tests made on these weights show that it has great promise as a platinum substitute. The weights have been under observation for two years, and have shown that stellite possesses great stability; weights made of it remaining constant to less than 1 part in 10,000,000 over that period.

A new gear-measuring machine was also exhibited; with this machine it is possible to measure the pitch of teeth, tooth-shape, and thickness, concentricity of teeth with the gear axis, parallelism of teeth with the axis, radial symmetry of teeth, and the pitch diameter. By ingenious arrangements the profile of the successive teeth can be magnified and made visible on a smoked glass and examined by projection methods, while the variation from uniform motion of two gears in mesh can also be critically examined.

A travelling microscope, in which many of the errors prevalent in the usual form of travelling microscope are eliminated, was demonstrated. In addition, the instrument, by suitable gearing, gives results simultaneously in inches and centimetres to a ten-thousandth of an inch or centimetre.

The exhibits in the Electrotechnics Division included the experimental arrangements for precision resistance measurements, for research on buried cables, for the determination of the errors of current transformers, and for the photometric measurement of lamps. An interesting demonstration of the attraction of the suspended particles in oil to electrodes at high potentials showed how such impurities can diminish the insulating properties of oils used for insulating high-tension apparatus. The illumination building in which experiments on the window efficiency of rooms are carried out was also open for inspection.

The end hardening of gauges, which was investigated in conjunction with the Metrology Department, was also shown here. The gauge is made one electrode in a furnace and passes a heavy current through a piece of graphite, which is thereby heated to a high temperature. The portion of the gauge in contact with the graphite thus attains a temperature considerably above the critical temperature for steel, and on dropping into water all the portion which was above the critical temperature is very effectually hardened. In this way only a very small proportion of the material of the gauge is interfered with in the hardening process.

The Wireless Division's exhibits consisted of apparatus for measuring both the direction and intensity of the electro-magnetic field from a distant radio transmitting station, and for applying these measurements to the study of the propagation of electro-magnetic waves over the earth's surface. To assist in this study of radiation problems, a transmitting station using both damped and undamped waves has been erected. An earth screen is employed at this station with various forms of antennæ. Apparatus was also shown for the absolute measurement of the amplification produced by a valve amplifier at audio-frequencies: this is used for the testing and investigation of both valves and their coupling transformers.

In the Radiology Division a Bragg spectrometer was shown in operation for the examination of the structure of metals and alloys. The method is a modification of the powder method of determining crystal structure, and has been extended to several systems of alloys, including copper and aluminium, copper and nickel. In each case it is found that in solid solution the solute atom enters into the lattice of the solvent by substitution. The structures of such metallic compounds as $CuAl_2$ and AgMg have also been determined by this method. Apparatus consisting of a spherical ionisation chamber for the investigation of the scattering of X- and γ-rays was also shown. This problem is of interest in connexion with deep therapy treatment using X- or γ-radiations, where, unless suitable precautions are taken, it is possible to obtain several times the desired exposure due to the scattering effect of surrounding tissues.

In the General Physics and Heat Divisions the exhibits were mainly of apparatus for determining the thermal constants of materials. Among these were a special calorimeter for use with substances that react with water, new forms of immersion

heaters for use at high temperatures, and apparatus for determining the thermal conductivity of metals up to within a few degrees of their melting-points. Other apparatus exhibited was concerned with the production of sounds of constant intensity and frequency, and with the reflecting and absorptive properties of materials for sound waves. A high vacuum two-stage mercury pump was also shown, by which pressures of less than 10^{-6} mm. of mercury can be obtained with a supporting pressure of 4 mm. of mercury. The exhaustion speed for both gases and vapours is extremely high, and drying chemicals are unnecessary. The pump and its connexions throughout are of steel, and the system is vibrationless and noiseless.

Among other important exhibits in the Metallurgy and Chemistry Departments was an induction furnace in which metals of the highest melting-point can be readily melted by the agency of eddy currents induced in them from a surrounding high-frequency current. Models illustrating the internal constitution of alloys consisting of three or four metals were also shown, together with a number of interesting microphotographs showing the structure of copper containing oxygen and the deformation of metals under the action of cutting tools.

In the Optics Division various forms of apparatus used in colorimetric work were on view, together with demonstrations of the methods used in determining the optical constants of lenses, prisms, optical glass, and the performances of optical instruments. An interesting and simple shadow method of showing up striæ and lack of homogeneity in glass was shown.

In the Electrical Standards Division various methods of measurement of electrical properties at radio- and audio-frequencies were demonstrated.

River-terraces and Glacial Episodes.

A. PENCK'S view, that the infilling of valleys with glacial detritus in Central Europe indicates an ice-extension, while the subsequent erosion of the deposits indicates an ice-retreat and therefore an interglacial episode, has received wide acceptance, and has been applied to areas where other causes may have brought about the facts observed. A. Heim in Switzerland has kept in view the effect of general movements of elevation or depression on river-erosion and valley-choking respectively, and teachers in the British Isles are not likely to have omitted such factors from their explorations of existing features in the homelands. W. Soergel, on the other hand (see NATURE, vol. 108, p. 464, 1921) has felt that the infilling of the valleys round the Rhine-vale and the subsequent erosion must be due to climatic changes rather than to earth-movement, and that much of the infilling is due to frost-action.

There seems to be a feeling in Holland that valley-terraces and "drift" accumulations in the northern lowlands have been unduly linked up with those of the Alpine area, and Prof. J. van Baren has issued a critical paper in English, bearing the long but expressive title, "On the correlation between the fluvial deposits of the Lower-Rhine and the Lower-Meuse in the Netherlands and the glacial phenomena in the Alps and Scandinavia" (Mededeelingen van de Landbouwhoogeschool, 1922; Wageningen: H. Veenman, 1922; price f. 2.50). He lays stress on changes in the position of the sea-level and on tectonic movements generally, and even ascribes to the latter many cases of disturbance in deposits that have been regarded as glacial and as pressed on by the Scandinavian ice-front. In his desire to be free from the incubus of glaciers in the central and northern Rhine-vale, he reverts (p. 13) to the old suggestion that rock-surfaces may be striated by the sliding of stones down mountain-slopes. There is a good deal in recent Dutch discussions of the subject that van Baren desires to make more widely known, and a good deal that will seem to be a challenge to British workers, who have felt that sound conclusions have been reached in regard to the problems of the East Anglian "drifts." The author's beautiful photographic illustrations show how much may be done with the unpromising materials of modern clay-pits.

Dr. C. H. Oostingh (Ber. Oberhess. Gesell. für Natur u. Heilkunde zu Gieszen, vol. 8, 1922) treats of the "Geschrebe südhicher Herkunft in Holland und den benachbartein Gegenden," and, like van Baren, is opposed to the suggestion of any glaciation by land-ice of the hills about the central Rhine. He regards the blocks from the south, of which he has made careful collections throughout Holland, and which are very often angular, as transported by ground-ice floating down the rivers. He asks also for more complete petrographic information as to the materials in the English Forest Bed that have been attributed to the denudation of Germany and the Ardennes. His extensive bibliography will aid numerous English workers in this field.

University and Educational Intelligence.

BIRMINGHAM.—At a degree congregation held on July 7, the Vice-Chancellor (Sir Gilbert Barling) conferred the honorary degree of Doctor of Laws on Dr. F. W. Aston, in recognition of his distinguished contributions to scientific knowledge.

The degree of D.Sc. was conferred (*in absentia*) on Mr. C. S. Fox for a thesis on "The Bauxite Deposits of India," and other papers on geological subjects. The degree of M.D. was conferred on the following:—J. C. Brash, C. C. Elliott, R. J. Gittens, A. P. Thomson, and G. H. Wilson. There were 26 successful candidates for the degree of M.Sc., 94 for the honours B.Sc., 68 for the ordinary B.Sc., and 29 for the degrees M.B., Ch.B.

BRISTOL.—Prof. J. W. McBain is to give a dedication address in connexion with the opening of the Chemical Laboratory at Brown University, Rhode Island, United States.

The degree of Bachelor of Agriculture (B.Agr.) has been established in the Faculty of Science. The curriculum for the degree occupies 5 years, two of which will be spent in the University (including the Agricultural and Horticultural Research Station, Long Ashton), two years in the Royal Agricultural College, Cirencester, and the remaining year on a selected farm.

CAMBRIDGE.—Mr. G. C. Steward, fellow of Gonville and Caius College, has been appointed fellow and lecturer in mathematics at Emmanuel College. Mr. A. H. Davenport has been appointed fellow and bursar of Sidney Sussex College.

The Syndicate appointed to consider the regulations for the Jacksonian professorship on the vacancy caused by the death of Sir James Dewar, recommend that it be defined to be a professorship of natural experimental philosophy as relating to physics and chemistry, and suggest that a professor should be appointed whose work would advance the knowledge of chemical physics on the lines of recent physical, atomic, and molecular research. The exact method by which such researches may lead to finding a cure for the gout—one of the prime duties of the professor according to the will of the founder of the chair—may at present be left to the speculations of the curious.

The Chemical Department Syndicate has issued a

report on the extension of the buildings of the Chemical Laboratory, showing an expenditure on buildings and equipment during the last four years of more than 75,000*l*. The annual report of the Observatory Syndicate refers to work on proper motions of stars, by plates exposed through the glass and measured superposed film to film on old plates taken with the Sheepshanks Equatorial 15 to 20 years ago. The chief points of interest in the report of the director of the Solar Physics Observatory are an account of Mr. C. T. R. Wilson's most recent work on β-ray tracks, continued investigation on the distribution of calcium flocculi and prominences on the sun, the preparation and publication of a revised list of unknown lines in celestial spectra, and work on coarse diffraction spectra by crossing a prism and a grating as originally suggested by Prof. Merton.

The Jubilee Celebration of the Cambridge University local lectures was celebrated on July 6-9 by a conference on various aspects of extra-mural teaching.

ST. ANDREWS.—Prof. J. Read, professor of organic chemistry (pure and applied) since 1916 in the University of Sydney, has been appointed to the chair of chemistry and the directorship of the Chemistry Research Laboratory. Prof. Read may be regarded as the founder of the first school of organic chemistry in the Southern Hemisphere.

RESEARCH bureaus have, during the past three or four years, been created by boards of education in many large and some small cities in the United States. Ten years ago there were none of these organisations: now there are upwards of 45. An account of the constitution and functions of a score of them, published last January by the Bureau of Education, Washington, shows that while in every case they collect and digest facts relevant to the problems with which the boards have to deal, they vary widely in importance and scope. Some resemble the cost-accounting department of an industrial concern, others a military intelligence branch, and all have something of the character of the special inquiries and reports department of our own Board of Education. A city in which this kind of development has been most noticeable is Detroit. Here a highly enterprising and influential Department of Instructional Research has been at work since 1914, formulating educational policies to be carried out throughout the city-school system and watching their operation. It works through its own staff-director, three assistants, four regular clerks, from three to twelve extra clerks, and a department of supervision with separate sections for health, English, exact sciences, social sciences, vocational education, and fine arts, and in close association with a department of special education responsible for psychological measurements, assignments to proper classes and direction of education of "atypical" children. A separate Bureau of Statistics and Reference, with five officers and eight clerks, was organised in 1918. At Indianapolis the research department cost in 1921–22 11,500 dollars, and "in dollars and cents has more than paid its way in watching leakages in receipts and expenditures, and in suggesting more efficient methods of doing things with smaller expenditures."

THE West Indian Agricultural College in Trinidad, which was opened on October 16, 1922, by Sir Samuel Wilson, Governor of Trinidad and Tobago, has now nearly completed the first academic year of its existence, and this first year has been one of great promise and encouragement. *Via colendi haud facilis* —the motto chosen for the College—is a very apt one, and it is well that those in authority with regard to Colonial affairs at home have come to regard tropical agriculture as so serious a pursuit that it has been deemed necessary to found a college for the study of tropical agricultural matters. The prospectus for the coming academic year has just been issued, and in addition to containing information as to College regulations and administration, it gives detailed particulars of the various courses of instruction. Arrangements are made for a diploma course which occupies three years and leads up to a diploma in tropical agriculture. Facilities are also afforded for special study by graduates of other universities and colleges who desire to extend their knowledge of subjects pertaining to tropical agriculture, and to undertake investigations into these matters under tropical conditions. Arrangements for a course in sugar technology, which is one of the subjects for the diploma course, are not yet fully completed, but it is proposed to erect a model sugar factory without delay. It is to be hoped that officers trained in British colleges and universities who have been selected to fill agricultural posts in the Colonies will either be sent to Trinidad to take a special course of study before taking up their appointments, or will be given facilities for carrying out special research at the College during one of their periods of leave. If the College can be used for the further training of our Colonial agricultural officers in the manner suggested, very great benefits will accrue to agricultural enterprises throughout the Empire.

THE Imperial Education Conference, opened by the Duke of York on June 25, concluded its sittings on July 6. This is the second conference officially convened, the first having been held in 1911. A previous conference, held in 1907, was organised by the League of Empire. The current conference was fully representative of education within the Empire in its official aspects. The Irish Free State and Northern Ireland were represented for the first time. The subjects discussed included the qualifications of teachers and mutual recognition of teachers' training and service throughout the Empire, vocational training, leaving certificates, rural education, the bi-lingual problem, native education, and various administrative questions. On the question of school examinations, Dr. H. Murray, of Nova Scotia, made the important suggestion that certificates should state the subjects taken and the percentage of marks gained in each subject, the several universities being left to determine whether or to what extent each certificate should be accepted for matriculation. He thought that, except in special subjects, the value for the Dominions and India of external examinations conducted by examining bodies in Great Britain was apt to be overrated. Mr. W. T. McCoy, of South Australia, urged the establishment of a Bureau of Education for the Empire. He acknowledged the excellent work done by the Department of Special Inquiries of the English Board of Education, but pointed out that there was no book or authoritative publication which supplied information and statistics of education in the Empire in a handy form. To the maintenance of such a Bureau, he suggested, all the dominions, colonies, and dependencies should contribute. In the evenings addresses were given followed by discussion, the most important being by Sir Robert Baden-Powell on character training and a brilliant address by Sir Charles Lucas on "The Island and the Empire." An educational exhibition was organised in the Home Office Industrial Museum and Westminster Training College, which was opened by Mr. Wood, president of the Board of Education. Hospitality was lavishly provided for the delegates, including a dinner given by the Government, under the presidency of Mr. Wood.

Societies and Academies.

LONDON.

The Royal Statistical Society, May 19.—A. L. **Bowley**: Death-rates, density, population and housing. The death-rates and infant mortality rates in the urban districts of England in the years 1911–13 were examined with a view of testing their relationship to the crowding of town populations. In Greater London, for example, the death-rate in districts where on the average there were 100 people to 100 rooms tended to be 12·7; where there were 110 people to 100 rooms 13·9, and so on in arithmetical progression. Six regions were considered separately, namely, Greater London, South of England, Lancashire and the West Riding, North-eastern coal district, Birmingham and South Staffordshire, and the North of England. In the North, generally speaking, the death-rates were higher and crowding and overcrowding more prevalent than in London and the South.—J. C. **Dunlop**: The misstatement of age in the returns of the census of Scotland. Age-periods, one including ages under 6 and the other ages 17 to 92, were discussed. A considerable amount of error persists, but greatly reduced in quantity—a change at least partly ascribable to an alteration of the wording of the age question in the schedule issued to householders at the census of 1921.

Royal Meteorological Society, May 20.—Dr. C. Chree, president, in the chair.—J. E. **Clark** and I. D. **Margary**: Report on the phenological observations in the British Isles, 1922. An exceptionally cool and sunless summer was experienced after mid-June. Before this a fairly mild winter followed by a cold early spring made fruit blossom late. Heat and sunshine of exceptional intensity signalised the latter part of May and early June, resulting in unusually rapid flower and insect development. Ripening was very late, however, especially in the north and Highlands, much hay being ruined or not cut till late September. The dry October and November enabled southern farmers to get well ahead with ploughing and sowing. The isophene flower chart shows little divergence from the lines giving the 30 years average, on account of the acceleration due to May and June. The migrant records indicate a similar sudden speeding up of their movements. As a consequence of the previous favourable summer and autumn there was a remarkable display of blossom and fair fruit crops despite the untoward summer.—T. G. **Longstaff**: Meteorological notes from the Mt. Everest expedition of 1922. A systematic record of temperature was kept on the outward march, at the base camp at 16,500 feet, and at the various climbing camps. Night temperatures were taken with minimum thermometers exposed to the sky on wooden boxes about one foot above the ground. Day temperatures were taken with sling thermometers. The lowest night temperature experienced on the outward march, April 12 to May 1, was 8° F. on April 13 and 19, at a height of 14,000 ft. The mean reading was 15° F. The lowest night temperature recorded during the expedition was −12° F. on May 27 at Camp III. at a height of 21,000 ft. The notes refer only to April, May, and part of June, and on the northern side of the main Himalayan axis of elevation. Totally different conditions prevail on the southern side, and the change from one to the other is abrupt. On the north side of Mt. Everest the snow-level is put at 20,000 ft., and glaciers descend to 16,500 ft. Owing to extreme dryness, evaporation is very rapid. Above 25,000 ft. snow disappears quickly with melting. Probably the constant high winds greatly assist this phase.

Optical Society, June 14.—Mr. T. Smith, vice-president, in the chair.—S. G. **Starling**: Levels and level bubbles. The factors affecting the efficiency of levels of the bubble form are discussed. Benzol, xylol, chloroform, alcohol, and ether are used in levels; the physical properties of these, and also of petroleum ethers distilled at various ranges of temperature, are given. A new method is described of obtaining calibration curves, by photographing the image of the bubble in a plane mirror, so that the position of the bubble upon the scale is obtained for successive tilts given to the tube. The relations between temperature and width and depth of bubble are obtained, and the results applied to an explanation of the "constant" bubble of Messrs. E. R. Watts and Son, Ltd., which has the same length at all temperatures.—E. W. **Taylor**: The primary and secondary image curves formed by a thin achromatic object glass with the object plane at infinity. The shapes of the primary and secondary image curves formed by a thin simple lens of an object plane at infinity can be readily determined. The image curves in the case of a double object glass of ordinary thickness, and with the inner curves approximately in contact, correspond very closely to those of a simple lens of the same power, and are only very slightly affected by the use of different glasses.—T. F. **Connolly**: A new form of balloon theodolite. The instrument is designed primarily for the observation of drifting balloons where it is desired to follow closely and consecutively the movements of the balloon and to note periodically the time and the simultaneous altitude and azimuth observed. The horizontal and vertical circles are brought together in such a way that a single index serves for reading both. A large field achromatic magnifier is so arranged that a "stand off" view is secured. The usual vernier has been abolished and replaced by a single index. Estimations of the degree intervals are made on each circle to 0·1°.

Geological Society, June 20.—Prof. A. C. Seward, president, in the chair.—K. S. **Sandford**, A. S. **Kennard**, B. B. **Woodward**, and R. C. **Spiller**: The river-gravels of the Oxford district. Ancient river-terraces occur in the headwater region of the Thames basin, west of the Chilterns, and maintain the same curve as the thalweg of the present rivers with which they are associated. There is no discontinuity of the terraces of the headwater tributaries of the Thames at their confluences near Oxford. Three terraces are identified above the present flood-plain. Below the lowest are flood-plain gravels, and a sunk channel has been identified. Each terrace contains a warm-climate fauna, with *Elephas antiquus*. The Proboscidea are represented by a suite of forms, from *Elephas antiquus* of archaic characters to the Siberian mammoth. The warm-climate fauna lingers long in the area. Palæolithic implements are scarce; unabraded specimens are of Acheulean culture.—L. **Dollo** and P. T. **de Chardin**: The deposits of Palæocene mammalia in Belgium. The four known deposits in Belgium at Erquelinnes (Hainaut), Orsmael (Brabant), Leval (Hainaut), and Vinalmont (Liège), containing Palæocene mammalia, are of Sparnacian age (=Upper Landenian). They have yielded remains of marsupials, Insectivora, Carnivora, rodents, Condylarthra, Amblypoda, perissodactyls, and primates. No remains of Thanetian mammalia have been discovered in Belgium, and therefore the continuance into the Sparnacian of Belgium of the genus Adapisorex recorded from the Thanetian of Cernay is noteworthy.

Paris.

Academy of Sciences, June 18.—M. Guillaume Bigourdan in the chair.—M. **Mesnager**: An indefinite thin plate, uniformly loaded, supported by points regularly spaced.—Marcel **Brillouin**: The possibility of studying the phenomena of radiotelegraphy on reduced models. A model constructed on the scale of one-thousandth could be made to serve many useful purposes. The modifications necessary to secure similitude are discussed.—P. **Sergesco**: Symmetrisable nuclei.—Serge **Bernstein**: The extremal properties of polynomials and of integral functions on a real axis.—Bertrand **Gambier**: Minimal curves: curves of constant torsion: Bertrand curves. The deformation of the paraboloid and hyperboloid of revolution.—A. **Petot**: The mode of working of automobile brakes.—Etienne **Œhmichen**: The flights carried out at Valentigney (Doubs), on April 28 and May 1, 1923, on the helicopter "Œhmichen-Peugeot, No. 2." A detailed account of two flights with this machine.—Max **Morand**: The electromagnetic radiation of electrified particles.—L. **Fraichet**: The magnetic testing of steels under traction. Elastic limits. The variations in the magnetic state of a steel under varying load show a permanent molecular change at a point named by the author "the true elastic limit." This point is lower than that corresponding to a permanent extension of the bar; the ratio between the "true elastic limit," thus defined, and the limit of proportionality is 0·7 to 0·95 for ordinary steels after annealing, and 0·5 to 0·65 in ordinary steels after tempering.—Paul **Woog**: Some phenomena of the superficial alteration of glass, capable of detection by high-tension currents. The phenomena described depend upon the presence of a layer of sodium carbonate on the glass and its absorption of traces of water from oil, resulting in changes of electrical conductivity.—Léon **Guillet** and Marcel **Ballay**: The influence of cold hardening on the resistance of metals and alloys. The changes in the electrical resistance of metals produced by cold hardening are less than 4 per cent. All the pure metals examined (except lead and tin) showed increased resistance. A brass (68/32) showed a 21 per cent. increase of resistance. In all cases, annealing restores the original resistance.—A. **Dauvillier**: Paramagnetism and the structure of the atom.—P. **Job**: The complex ions formed by silver salts and ammonia or the substituted ammonias. The equilibrium constant of this reaction has been studied by measuring the potential differences between a silver electrode and two solutions containing silver nitrate and silver nitrate plus amine at varying temperatures. Results are given for ammonia, diethylamine, ethylenediamine, and hexamethylenetetramine.—Marcus **Brutzkus**: Contribution to the theory of internal combustion motors.—L. **Hackspill** and A. **Conder**: In the ordinary method of manufacturing liquid carbon dioxide, the gases from the combustion of coke are absorbed by cold potassium carbonate solution, and the pure carbon dioxide required for compression recovered by heating the potassium bicarbonate solution thus obtained. Investigation of a case of rapid corrosion of the condenser of a compression plant showed that ferric nitrate was being produced. This has been traced to oxides of nitrogen produced during the combustion of the coke. These are fixed by the alkali, but small quantities of nitric oxide can arise from the interaction of carbon dioxide and potassium nitrite, and this is the source of the corrosion.—Max and Michel **Polonovski**: Di-iodomethylates in the eserine series.—Mlle. **Brepson**: The formation of soils in the region of Saulieu (Morvan). In this region the process of soil formation is simple, and is due to the decomposition of the subjacent rock under the influence of atmospheric agents: the action of wind or streams plays only an insignificant rôle.—J. **Barthoux**: Observations relating to the genesis of certain manganiferous deposits.—C. E. **Brazier**: The magnetic agitation at Parc Saint-Maur and at Val-Joyeux, and its relation with solar activity. The variations of the solar activity show no relation with the position of the earth in its orbit, while the magnetic agitation has a clear seasonal variation. For this reason the amplitude of the annual variation of the magnetic agitation is compared with the solar activities, 10-year periods corresponding with definite solar conditions being chosen. This annual variation of amplitude follows fairly well the changes in the solar activity.—Fernand **Obaton**: Experimental researches on the reddening of cherries. The reddening of cherries depends on the temperature, and light has no direct action on the phenomenon: a study of the respiratory coefficient showed that an absorption of oxygen accompanies the reddening process.—A. **Goris**: The chemical composition of *Monotropa Hypopitys*.—Ch. **Kilian**: Coefficients of utilisation and velocity of growth in fungi.—Emile **Haas**: The undulation of fatigue in different regions of the spectrum.—A. **Desgrez**, H. **Bierry**, and F. **Rathery**: The action of insulin on glycæmia and acidosis.—P. **Benoit**: Ovogenesis and segmentation of *Myriothela Coksi*.—L. **Mercier** and R. **Poisson**: A case of accidental parasitism of a Nepa by infusoria.—A. **Policard** and G. **Mangenot**: Cytological researches on the condition of the oil in oleaginous seeds. The ripe seed.—Maxime **Ménard**: Ten cases of pregnancy after treatment of fibroma of the uterus by X-rays.—J. **Chevalier** and Fernand **Mercier**: The pharmacodynamic action of the insecticidal principle of pyrethrum flowers.

Perth (W.A.).

Royal Society of Western Australia, December 12.—Mr. E. de C. Clarke in the chair.—L. **Glauert**: (1) Contributions to the fauna of Western Australia, No. 3. A new species of burrowing crab is described. (2) *Cidaris comptoni*, sp. nov., a cretaceous echinid from Gingin. This is the first fossil sea-urchin to be described from Australian cretaceous formations. Affinities are noted with echinids from the white chalk of England and lower cretaceous beds of N. Africa, Sinai, and India.—R. J. **Tillyard**: The Embioptera or web-spinners of Western Australia. The history of the insects as revealed by Palæozoic fossils is described. The previously recorded *Oligostoma hardyi* and a new species, *O. glauerti*, are discussed.—L. **Glauert**: An annotated list of lizards from Wallal. The list includes one new species.—C. A. **Gardner**: Second contribution to the flora of Western Australia. Eight new species are described, one establishing a new genus and introducing the family Ericaceæ into the West Australian flora.

March 13.—Mr. E. de C. Clarke in the chair.—E. S. **Simpson**: Secondary sulphates and chert in the Nullagine series. In the softer beds of the Nullagine (Keweenawan ?) series, which covers large areas in the north-west of Western Australia, gypsum, epsomite, tamarugite, pickeringite, copiapite, alunite, and jarosite occur as vein fillings, efflorescences or imbedded crystals. Chert is widespread as hill-cappings and waste therefrom. The paragenesis of the minerals is detailed and their origin traced to weathering of pyrite and marcasite concretions which are abundant in the series. New analyses of the minerals are given, also the striking chemical

differences between the ground-waters of the Nullagine area and of the Dry Lake region.—L. **Glauert**: Contributions to the fauna of Western Australia, No. 4. A freshwater isopod, *Phreatoicus palustris*, sp. nov., recently found in the swamps and small lakes near Perth, is described. The animal is closely allied to species found on Mount Kosciusko (5700 ft.) and Baring Tops (5000 ft.) in New South Wales; on Mt. Wellington (3800 ft.), Tasmania; on Dividing Range (2000 ft.), Victoria; on Table Mountain (2000 ft.), S. Africa; and in New Zealand, blind, in wells. Its distribution suggests former land connexion between New Zealand, Australia, and S. Africa.—T. H. **Withers**: An Australian cretaceous cirripede. Additional material from Gingin shows that a barnacle previously described by R. Etheridge, junr., as *Pollicipes* (?) *ginginensis* is a species of Calantica (Scillælepas).

April 10.—Mr. E. de C. Clarke in the chair.—A. D. **Ross** and R. D. **Thompson**: Magnitude observations of the star Beta Ceti obtained since the recent reported outburst. The reported increase in intensity can be explained by the fall into the star of a body of planetary size.—E. O. G. **Shann**: The present position in international exchange. A critical discussion is given of the various schemes to regain stability.

SYDNEY.

Linnean Society of New South Wales, March 28.—Mr. G. A. Waterhouse, president, in the chair.—G. A. **Waterhouse** (annual address): (1) Biological survey of Australia. Attention was directed to the slaughter of Australian marsupials for the sake of their skins, and to the export of enormous numbers of birds. The scientific interest of the fauna is evidenced by the number of collecting expeditions visiting Australia. The protection of the flora is a necessary corollary of any attempt to protect the fauna, and support is given to a recent suggestion to preserve the forests of all those portions of New South Wales which are more than 4000 feet above sea-level. (2) A further account of breeding experiments with the Satyrine genus Tisiphone. An account of the family from an orange female caught at Port Macquarie, April 17, 1922. This female had probably not laid any eggs before her capture, and she laid 14 eggs in captivity, from which 12 butterflies were obtained. The family shows, in the general shape of the forewing markings and the absence of the hindwing band, a closer approximation to *abeona* than to *morrisi*; the colour of three-fourths of the specimens is that of *abeona* rather than *morrisi*, but the size and coloration of the ocelli approximate rather to *morrisi* than *abeona*.

Mr. A. F. Basset Hull, president, in the chair.—R. **Greig-Smith**: The high temperature organism of fermenting tan-bark. Pt. ii. In the process of white-lead manufacture, the spent bark, before being again used, is subjected to a preliminary fermentation in which moulds play a part. Several that were isolated were able to convert cellulose into soluble products capable of being attacked by the high-temperature organism. The tempered bark contains humic acid as a typical constituent, and this substance is fermentable. Tempering is clearly a biological process in which the woody matter of the bark is altered to substances that can be fermented by the high-temperature bacterium.—J. **McLuckie**: Studies in symbiosis. No. 3. A contribution to the morphology and physiology of the root-nodules of *Podocarpus spinulosa* and *P. elata*. The development of the root-nodules of these two species of Podocarpus, the method of infection of the roots by the bacteria, the distribution of the bacteria in the cells, and of the fungal hyphæ which are frequently present, are discussed. The nitrogen-fixing power of the organism causing the nodule formation has been estimated.—G. F. **Hill**: New Termites from Central and South-East Australia. One new species of Coptotermes and two new species of Eutermes are described. The Australian termite fauna now comprises 6 species of Coptotermes and 28 species and 1 variety of Eutermes.—T. G. **Sloane**: Studies in Australian entomology. No. xviii. Synoptic tables of the Australian species of the genera Dyschirius, Craspedophorus, and Dicrochile are given, and a table of genera of the tribe Odacanthini—introducing 2 new genera.

CALCUTTA.

Asiatic Society of Bengal, June 6.—S. L. **Hora**: The adhesive apparatus on the toes of certain geckos and tree-frogs. It appears probable that all such adhesive apparatus consist of mere friction devices.—M. J. **Seth**: A manuscript Koran in classical Armenian.—L. R. **Rau**: On the age of the Uttatur marine transgression. The fossils in the lowermost Uttatur deposits and their correlation with foreign equivalents appear to show that the term "Cenomanian transgression," now generally employed for this encroachment of the sea on land in Southern India during cretaceous times, does not faithfully represent it in point of time and has to be modified so as to accord with an older age.—R. **Chanda**: (1) Note on the discovery of supposed Neolithic writing in India. The inscription on one neolith is evidently a modern date in Arabic numerals. The other object is not a neolithic artifact, and the letters are probably scratches. (2) Prof. Mazumdar on the dates of the Sanchi inscriptions. A fifth test letter, *dha*, for distinguishing post-Mauryan Brahmi.—N. K. **Majumder**: Siddhānta-Sekhara of Sripati. A brief introductory account of an important treatise on Indian astronomy, Siddhānta-Sekhara, by the reputed Indian astronomer, Sripati, of the eleventh century A.D. Recently a copy was discovered in the Trivandrum Palace Library, and a few other copies in the Government Oriental Manuscripts Library of Madras.—C. B. **Kloss**: On Blyth's bulbul (*Xanthixus flavescens*). Specimens from North Cachar are sufficiently different from specimens collected in Arrakan to be accepted as representing a new sub-species.—P. C. **Mahalanobis**: A first study of the head-length of Bengal castes and tribes. A biometrical analysis of the head-length of 36 Bengal castes and tribes.

Muscular Exercise.[1]

By Prof. A. V. Hill, F.R.S.

Introduction.—Muscular exercise is a subject in which most people are interested. It is fortunate therefore that, in this direction, physiology has made greater progress into the intimate working of the body than perhaps in any other. The means by which bodily movements are carried out is muscle. Muscle is the red meat. There are three kinds of muscles: the voluntary muscle of the trunk and limbs, governed—or at any rate governable—by the conscious will of the individual; the involuntary muscle of the blood-vessels, of the alimentary and excretory, the so-called vegetative, system; and the cardiac or heart muscle, the muscle which pumps the blood round the body.

Muscle from the microscopic point of view is made up of a large number of similar thin fibres, about $\frac{1}{500}$ inch in diameter, and made of a jelly-like substance, running more or less parallel to one another. They are liberally supplied with minute blood-vessels from which they obtain their supplies of oxygen and food.

The voluntary muscle fibre is long and regular, and has obvious and characteristic cross-striations. The involuntary muscle fibre is smooth and long, with obvious nuclei, and generally occurs in thin sheets. It shows no sign of cross-striations. The heart muscle is vividly cross-striated, but its fibres are shorter and connected physiologically with one another, not running regularly in considerable lengths, their directions corresponding to the lines in which the walls of the heart are required to shorten, in order to expel the blood efficiently.

The voluntary muscle is excited by a voluntary, a so-called medullated nerve: the involuntary muscle by an involuntary, a non-medullated nerve: the heart beats automatically of itself, though its beats can be influenced reflexly through two nerves.

In function the muscles differ very widely from one another. The voluntary muscle moves very rapidly, indeed in some small animals the rapidity of its response is almost incredible—one knows the amazing quickness of a little bird jumping from twig to twig, but this is as nothing compared with the speed with which some small insects move their wings, a speed which one can detect from the high-pitched note they emit. The voluntary muscle is very powerful; it is usually "geared up" to increase the quickness of movement of the limb to which it is attached; if the flexor muscles of the arm of a powerful man were connected directly to a heavy load, they could lift a weight of about half a ton.

The voluntary muscle is very efficient for movements of moderate speed: it is very wasteful, however, if used to maintain a force for a long time, or if required to contract, either very rapidly or very slowly. The involuntary muscle, on the other hand, moves only very slowly: it takes seconds to perform what a voluntary muscle can do in a few tenths or hundredths of a second; it is very economical, however, in maintaining a force for minutes, or hours, for intervals maybe thousands of times longer than would be enough to produce complete fatigue in a voluntary muscle. The heart muscle moves at an intermediate speed: in man from 40 to 200 times a minute, depending on his health and training and state of exercise: in little animals faster, in large animals slower: it beats only—it never maintains a contraction—it would, so to speak, lift a weight up and down, but it could never keep it supported: it is amazingly infatiguable—it has a first call on the oxygen of the blood, and it can perform the most prodigious athletic feats.

A muscle's function is to "contract." The word contraction—drawing together—very well defines the activity of muscle: its volume does not alter when it contracts: like a piece of elastic it merely draws—or attempts to draw—its ends together. The sheaths of the muscle fibres are continued as tendons, and these tendons are attached to bones, so that when the muscle draws together the bones revolve about their common joint, and movements are produced. In heart muscle, the whole organ, in the form of two pumps, with inlet and outlet holes and suitable valves, is simply a closed vessel with powerful contractile walls which—by their drawing together—expel the blood into the arteries and around the body.

The fibres of voluntary muscle are bound together into anatomical and functional bundles—the so-called muscles—doing special duties in special ways and in special distributions. If a muscle be required to move through a long distance its fibres are parallel to the length of the muscle and long: if it be required to

[1] Discourse delivered at the Royal Institution on Friday, February 16.

move only through a short distance, but to exert a more powerful pull, its fibres run partly across the length of the muscle, they are shorter, and there are more of them: length of movement is sacrificed to strength.

Nervous Control.—The muscles have their activities controlled and co-ordinated by the nervous system. Partly this co-ordination is conscious and voluntary; mainly, however, it depends upon involuntary reflex control. In the body, in addition to the ordinary sense-organs is a complex and very important sensory system — the proprioceptive system — which deals mainly, or only, with the position, translation, and rotation of the body, with the stresses and strains in the muscles, with the positions and movements of the limbs. This system keeps the nervous system informed about the movements, passive or active, of the body, and about the strains and stresses, passive or active, of the muscles: and when anything happens, with amazing rapidity and almost unerring accuracy, the appropriate reaction is made, so that the balance or the posture is maintained, the integrity of the body is safeguarded, and the end in view is reached. Efficiency and skill at games, power and economy in violent effort, the faculty, in the literal sense, of falling on one's feet, all depend upon these quick, silent, overmastering, and generally unconscious reactions, dictated by the nervous system on the receipt of urgent messages from tendons, joints and muscles, or from the little sense organs associated with the ear.

Skill, power, and economy of muscular effort depend upon the effectiveness of these reactions; partly this muscular sense can be acquired, partly it is inborn, partly it is conscious or semi-conscious (though always inarticulate), partly it is reflex and instinctive: in any case it represents a highly developed and a very beautiful and important property of the nervous system. The instinctive skill, quickness, and economy of the gymnast or climber, of the mechanic, airman, tennis player, or athlete, depend upon a vivid and readily reproducible picture in the brain or nervous system, *a picture*, as Pear puts it, *of muscular exercise in terms of the sensations which effective and successful movements produce*. This lecture is intended to deal more particularly with quite another aspect of muscular exercise. To stress the energetic side of exercise, however, without any note on its intellectual and co-ordinative side, would give quite a false impression of the interest and variety of the subject.

Energetics.—Let us turn now to what one may call the energetics of muscular activity, of the capacity for doing work, or producing movement, of the cost of that work—of what we call "efficiency"—and of the conditions which limit that capacity—of what we call "fatigue." When a muscle contracts it can do work, which can be measured in gm. cm., or in ft. lb. This capacity for doing work seemed to physiologists to be the primary thing, until it was realised comparatively lately that *force*, rather than *work*, is the fundamental product of muscle. To maintain a state of contraction—even when no work in the mechanical sense is being done, as, for example, in pushing an immovable object, or in holding a weight at a fixed level—is just as tiring and expensive as actually to do mechanical work. The function of a muscle, therefore, is to pass from one state of stress to another state of stress without necessarily altering its length at all: if its load, or the resistance to its motion, be such that the muscle can shorten when its tension rises, it will of course do work in the mechanical sense: if, however, it maintain its state of tension without shortening at all, it will, none the less, require energy and become fatigued. Indeed, one knows that the most fatiguing exercise is to hold something, say at arm's length, without moving it up or down, without therefore doing any work at all in the mechanical sense.

Isolated Muscle. — Fortunately, for physiology, muscles can be isolated, and made to continue their function of contracting for days after removal from the body. It is easy to keep a frog's isolated muscle alive, in the sense at any rate that it will react to a stimulus, for many days. Moreover, the chief function of a muscle, indeed in a cold-blooded animal the only function, is simple and easy to detect and measure: the function of movement, of maintaining a posture, of exerting a force, is so extremely important to the animal that a very large proportion of its body has been devoted to this single highly differentiated purpose. Fortunately also it is easy to apply an artificial stimulus to a muscle, the electric shock, which produces no injurious effects and leaves the muscle ready to react again in a similar way a large number of times. A single sharp burst of electric current excites the muscle fibre to give the simplest and most fundamental unit of physiological response, the muscle twitch. In a twitch the tension rises, attains a maximum, and then falls again to zero, the whole cycle occupying anything from a small fraction of a second up to several seconds, depending upon the nature and condition of the muscle.

Now, in a voluntary muscle it is often—indeed almost always—necessary to maintain a force, or to exert a pull, for a finite and determinate time, not simply to give a tug and have done: and in such muscle this continuous pull can be produced by a rapid succession of stimuli each occurring before the effect of the previous one has passed off. One's own muscles do not appear to be obviously unsteady when exerting a voluntary effort: it can easily be shown,

however, by a delicate electrical device that 40 to 50 obvious vibrations per second occur in them, and that they are really reacting discontinuously to a rapid stream of stimuli: even the shortest voluntary contraction of which the human muscles are capable is due to a volley of impulses shot at it, along the nerves, by the brain. Each separate unit of effort, however, which goes to make up the complete contraction is expensive—each requires energy just as each stroke with a pump requires energy. It is obvious, therefore, why the *maintenance* of contraction is expensive and fatiguing.

Fatigue.—Nearly all the recent and important advances in muscle physiology have resulted from a study of the phenomena of fatigue. We all know that there is a limit to muscular exertion, a limit which is set by what we call fatigue. If an able-bodied man take exercise at a very small rate, *e.g.* by walking, he remains comparatively untired for long periods: if he takes exercise more violently he becomes tired more quickly: if he exerts himself with the extreme effort of which he is capable, he is completely exhausted in less than a minute. There are many different kinds of fatigue, but the one we are discussing now, from the study of which so much light has been shed on the nature of muscles, is the extreme athletic fatigue which results rapidly from very violent effort. By it the finest athlete in the world may be overcome within a minute. It is a simple and comparatively intelligible thing. We can reproduce it readily in isolated muscle, deprived of its circulation. Let us subject an isolated frog's muscle, every second or two, to an electric shock, and record its contraction · we find that the response changes in a regular and progressive way, the force exerted becoming less, the contraction being developed rather more slowly and continuing much longer, relaxation being much drawn out. Finally, the muscle becomes inexcitable. Now in the intact animal, in man, we know that even extreme fatigue is rapidly recovered from, and this recovery is attributed to the circulation. If the circulation be hindered by a cramped position recovery is slower. If the fatigued isolated muscle be left in a chamber free of oxygen, no sign of recovery occurs: if, however, it be left in oxygen, in a few hours complete recovery will take place, and the muscle will now be capable of repeating its previous effort.

The realisation, especially by Fletcher about twenty-five years ago, of the extreme importance of this observation led directly to the most striking advances in our knowledge of the working of muscle. Recovery from fatigue is possible only in the presence of oxygen, and it was natural to suppose that the oxygen was used to oxidise some waste product, the presence of which acted unfavourably on the muscle. The next great step was due again in part to Fletcher, this time in co-operation with Hopkins. Lactic acid was known to occur in muscle, and Fletcher and Hopkins found the lactic acid to be increased by exercise, and diminished or abolished by recovery in the presence of oxygen. Furthermore, there appeared to be a certain definite maximum, beyond which the lactic acid content of the muscle could not be driven, even by the most vigorous stimulation: clearly this corresponded to the maximum effort a muscle could make. What was the function of this lactic acid, was it indeed to be the keystone of the bridge which physiologists were building from physics and chemistry on one hand to muscular activity on the other?

Heat-production.—Muscles, in activity, give out heat. External mechanical work is produced by the muscle with an efficiency of only about 25 per cent. Hence for every 25 ft. lb. of energy turned into external mechanical work at least 75 ft. lb. are degraded into heat inside the body. In a maintained contraction, in which no actual work is done, all the energy used is turned into heat: while in such movements as running, the energy is indeed turned in part into kinetic energy, which, however, is chiefly reabsorbed into the body as heat, owing to the jolts and jerks and rapid movements of the limbs, just as the energy of a motor car on a bumpy road is absorbed largely as heat in the tyres. In a single muscle twitch the rise of temperature is only about 0·003° C., and if one wishes to measure to 1 per cent.—and for some purposes one must measure to 0·1 per cent.—it is necessary to read to the nearest 0·00003° C. This can, however, be done, and with the wonderful electrical measuring instruments now available it has become comparatively easy. It is worth doing, because the heat accompanies, and is a measure of, the chemical processes occurring in muscular activity, and its production can be followed continuously, and so made to give us the time course of those chemical processes.

If the electrical record of the thermal response of the muscle to stimulation be carefully analysed, it is found that the heat-production is by no means simple in its time relations. In the first place, if the muscle be in oxygen, there is an evolution of heat lasting for many minutes after the contraction is over: and this evolution of heat is not small, but actually larger in total extent than the heat which occurs early in the contraction. In the absence of oxygen this delayed heat almost disappears. Clearly it is somehow connected with the recovery process Fletcher had noticed in an exhausted muscle, which we all know in our own bodies; it is accompanied, as Fletcher and Hopkins had shown, by a disappearance of lactic acid. The recovery heat-production occurs more

rapidly at a higher pressure of oxygen. This agrees with what we know of recovery from exertion, or exhaustion, in man: breathing pure oxygen, instead of air, enormously increases its speed and completeness. Moreover, the magnitude of the recovery heat-production told one what happened to the lactic acid in recovery. One knew how much lactic acid was produced in a given contraction; one knew, therefore, how much lactic acid was removed in the complete recovery from that contraction: if it were all oxidised the heat evolved could be calculated: actually the amount observed is only about 1/6th of the amount calculated: hence the lactic acid removed in recovery, or at any rate its chief part, is not removed by oxidation, but in some other way.

Apart from this delayed heat-production associated with recovery, one might have expected the rest of the heat to be given out rapidly, more or less ex-

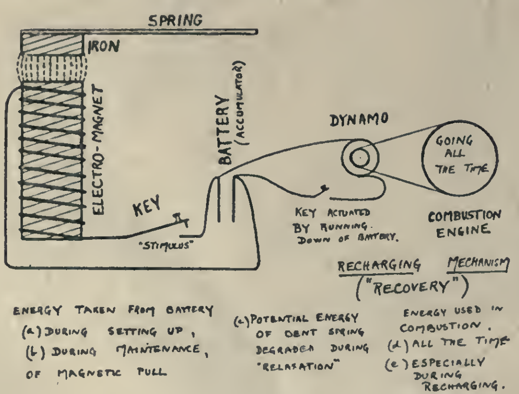

Fig. 1.—Electromagnetic analogy to the working of muscle.

plosively, at the commencement of contraction. Contraction has been likened to the explosion of a cartridge: the muscle suddenly gives out heat and develops force. This force, however, represents a state of elastic potential energy in the muscle, and when the muscle relaxes this potential energy disappears, and we should expect it to reappear as heat. Actually the analysis of the heat-production in the single twitch shows that about 60 per cent. of it is evolved in the initial process of setting up the contraction, 40 per cent. of it in the final stage of relaxation. If the contraction be prolonged, there is in addition a prolonged evolution of heat, lasting as long as the contraction, the rate of heat-production being proportional to the force maintained.

There are, therefore, four phases in the heat-production of muscle, corresponding (1) to the development, (2) to the maintenance, and (3) to the disappearance of the response, and finally (4) to recovery therefrom. A simple physical picture of the system is given (Fig. 1) by an electromagnet, pulling on a piece of iron attached to a spring: a key: a battery: and a dynamo (driven by a combustion engine of some kind) to recharge the latter. Energy is consumed in setting up the pull of the electromagnet, energy is being consumed all the time in maintaining the pull, energy—the potential energy of the magnetic field and the spring—is liberated when the current is broken, and energy is used in recharging the battery.

This picture has recently been given a more concrete chemical form. In contraction the lactic acid comes from glycogen; in recovery the lactic acid is restored as the glycogen from which it came, apart from a small proportion—about $\frac{1}{6}$th—which is oxidised to provide energy for the restoration. In the setting up of the contraction, therefore, lactic acid is liberated; in relaxation it is neutralised: it somehow produces the mechanical response by the action of its acidic part upon the structural protein elements of the muscle fibre. Protein is a weak acid at the hydrogen ion concentration of the body, and the structural elements of the muscle are in effect highly ionised sodium (or potassium) salts of protein. These structures therefore have a negative electric charge, all along their length, each element of the structure repelling every other element. The localised production of lactic acid causes the formation of sodium (or potassium) lactate, and of undissociated protein acid: the protein structure is discharged electrically: its elements cease to repel each other, and shortening occurs. It is well known that if the surface charge of mercury, in contact with sulphuric acid, be changed by conduction from outside, there results a change of surface tension, and so a movement of the mercury. This principle is utilised in the capillary electrometer, and would seem to have been employed by Nature in the muscle. The heat associated with contraction is due to the chemical formation of lactic acid from glycogen. As soon, however, as the lactic acid is free it is neutralised by the alkalies of the muscle, and relaxation sets in, the heat produced in relaxation being due to the chemical process of neutralisation. To maintain a contraction therefore requires a balance between the rate at which lactic acid is produced and the rate at which it is neutralised. Finally, in recovery, the neutralised lactic acid is slowly removed and restored, by the working of some unknown recovery mechanism, by which 5 parts of it are restored, and 1 part oxidised to supply the necessary energy.

Exercise in Man.—Our knowledge of the nature of muscular work in man has been derived largely from a study of the amount of oxygen used, and the various characteristics and time-relations of the oxygen supply. The subject of the experiment carries a large bag on his back (Fig. 2) and by means of a mouthpiece containing two valves, and a pipe and tap, he can breathe

in fresh air from the outside atmosphere and expire it all automatically into the bag. A sample of the expired air can be collected for any desired interval. An analysis of it, a measurement of its volume, and a knowledge of the composition of the inspired air, allow a determination of the oxygen taken in and the carbon dioxide produced. From these the amount of energy used by the man during the period in question can be calculated. A point immediately brought out is (as in the isolated muscle) that the oxygen must be regarded, not as being used during the actual exercise itself, but in recovery, each element of the oxygen consumption corresponding to recovery from a previous element of the exercise (Fig. 3).

FIG. 2.—Bag, pipe, tap, valves, and mouthpiece used to investigate the gaseous exchanges of man during running.

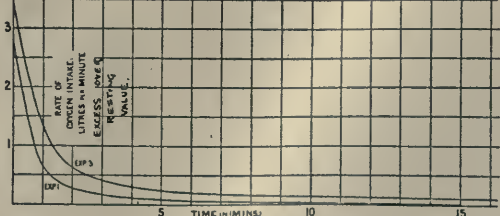

FIG. 3.—Oxygen intake in recovery after exercise: exercise ends at time o.

Many kinds of exercise have been investigated, for example bicycling, swimming, climbing, walking, running, ski-ing, and skating, and even the laborious process of pushing a motor bicycle up a hill! The two main types of muscular exercise are: (*a*) very violent exercise lasting for a short time, and (*b*) prolonged exercise of a more moderate kind.

Violent Exercise.—Let us take first the case of very severe exercise, for example, that of a man running 100 yards at top speed. The first personal impression which one forms of such severe exercise is that immediately after it, and often for a comparatively long time after it, panting occurs. The oxygen taken in is used almost entirely in recovery. In one experiment a good runner ran 225 yards in $23\frac{2}{5}$ seconds, and in the succeeding quarter of an hour recovered from his effort and used an extra $8\frac{3}{4}$ litres of oxygen in so doing. Such exercise, if it *could* be continued indefinitely, would require about 22 litres of oxygen every minute, but from other experiments the subject is known to be incapable of taking in more than about 4 litres per minute. Hence, during the most violent effort of which he was capable, he was using energy at about $5\frac{1}{2}$ times the rate that would have been possible had it been necessary for him to depend upon a contemporary supply of oxygen.

The "record" is held by a man of 46, who by means of a rapid quarter-of-a-mile run, followed by violent gymnastic exercise for 30 seconds, succeeded in making himself so exhausted that $13\frac{1}{2}$ litres of oxygen had to be used in recovery. This amount of oxygen would have maintained him quietly in bed for about an hour! It is clear that the body can get energy "on credit," which it has to repay after the exercise is over, by taking in later an extra amount of oxygen. It acts in the same manner as an accumulator, which can be run down at a very high rate for a short time and recharged afterwards. The discharge process is the formation of lactic acid from glycogen: in recovery this is reversed, the energy for the reversal being provided by combustion. The maximum lactic acid production in the muscle determines the limits of exercise, and the magnitude of the "maximum oxygen debt."

Prolonged Exercise.—Let us now discuss the case of exercise continued for a long time. By the most extreme effort of the respiratory system, a healthy man can take in about 4 litres of oxygen every minute. Consider, then, the case of a man taking exercise for a long time, say for an hour, during which time he will take in and use anything from 150 to 240 litres of oxygen. An oxygen "credit" even of $13\frac{1}{2}$ litres is only a small fraction of the oxygen which he can actually take in during the hour of exercise. Hence, he is limited in such types of exercise, not by the magnitude of the "debt" to which the body can submit, not, that is to say, by the lactic acid maximum of his muscles, but chiefly by the maximum rate at which he can take in oxygen. The oxygen is brought to the

lungs by the movements of respiration, thence diffuses through the lungs into the blood, which is pumped round the body to the active limbs and muscles. The amount of oxygen, however, which can be carried by the blood is comparatively small, namely, only about $\frac{1}{8}$th of its total volume.

The efficiency of the mechanism by which the oxygen is carried round in the circulating blood depends very largely on the efficiency and capacity of the heart. For prolonged vigorous exercise a powerful and efficient heart is essential. If, however, the lungs be too small the oxygen pressure in them will fall too rapidly when a given amount of oxygen is carried away by the blood, and the smaller the lungs the shorter will be the time (for a given blood-flow) during which each drop of blood lingers in them in contact with the air. The smaller the lungs, therefore, the less opportunity will the blood have of collecting its required oxygen: the smaller the lungs and the less efficient their ventilation, the lower will be the pressure of oxygen in the arterial blood.

Now the heart is an extremely vigorous and hard-working organ, and it has the first call upon the oxygen which is carried by the blood. The coronary artery takes blood directly from the aorta, and carries it round the heart muscle itself. If the lungs be small, or their ventilation inadequate, or their walls too impermeable, the pressure of oxygen in the arterial blood will begin to fall; consequently the heart itself will get a lower pressure of oxygen—it will slow up or give a less effective beat, the blood-flow will be slowed, and the oxygen pressure in the blood will rise again to another higher value. Thus a balance will be reached in which each unit in the double mechanism is working at its limiting capacity, and one will find in athletes, who are capable of long-continued effort, that there is a combination of (*a*) a vigorous and efficient heart, and (*b*) capacious lungs capable of rapid and extensive ventilation.

A vigorous output of blood by the heart requires a vigorous return of blood to the heart. On the venous side of the small capillaries which feed the muscles with oxygen, there is little pressure left to drive the blood along to the heart. In the veins, therefore, the flow of blood is largely determined by the activity and movements of the body. The veins are provided with valves, and the alternating movements of the limbs and muscles help to pump the blood along the veins. If the body be rigid the arteries and capillaries are constrained and the blood-flow is hindered, while the veins get none of the rhythmic changes of pressure which tend to pump the blood along them, and so they fail to supply the heart with blood. Such exercise as holding oneself up with arms bent, in a gymnasium, on a pair of rings, is not in itself violent, and would not, if it *could* be continued, require an amount of oxygen comparable with running, even at so slow a pace as eight miles an hour. In such exercise, however, an extremely violent contraction in the very muscle that requires the energy almost entirely prevents the supply of blood to it, no oxygen is received, lactic acid rapidly accumulates, and exhaustion sets in.

Similarly, in such types as rowing, in which part of the body is in a state of stress during a large part of the time and the rhythmic movements are relatively slow, the supply of oxygen is more difficult. Consequently rowing appears to strain the heart more often than other kinds of athletic effort. For an easy and vigorous circulation no exercise seems to compare with running on the flat; here the movements are very rapid and the muscles are rigid during only a fraction of each cycle; consequently the blood can run through very easily, and it gets helped along in the veins by the jolts and jerks and shakes which the body receives, and by the rapid rhythmic pressures which are applied to the veins by the movements of the limbs. Thus from the point of view of taking as much exercise in a given time, with as little strain on the heart as possible, running is probably superior in type to any kind of exercise.

The function of the heart in exercise is so important that a vivid appreciation is desirable of the extraordinary tasks it sometimes undertakes. A subject of $11\frac{1}{2}$ stone weight succeeded in taking in about 4·2 litres of oxygen in a minute, while running round a track at about 9 miles per hour carrying a bag and breathing through valves and mouth-piece. Now the amount of oxygen which the blood can take in and give out, as it circulates once through the body, is certainly not more than about $\frac{1}{7}$th of its own volume. Hence at least 7 times 4·2 litres of blood per minute, *i.e.* about 30 litres, were circulating round his body during this experiment. The largest water-tap in an ordinary house has an output which is poor when compared with that of a human heart. It is little wonder that the heart goes wrong sometimes: the wonder is that this happens relatively so seldom.

An Example from Athletics.—The way in which the capacity of the body for exercise depends upon the supply of oxygen, actual or potential, can be illustrated by an example from athletics. A certain subject is capable of taking in about 4·2 litres of oxygen per minute; let us assume that his maximum oxygen credit is 13·2 litres, as found by Lupton in another subject. Suppose that at the end of a race his oxygen supply, actual or potential, is completely exhausted. Then clearly if he runs for a minute he has $(4{\cdot}2+13{\cdot}2)=17{\cdot}4$ litres to spend altogether: if he runs for two minutes $(2\times4{\cdot}2+13{\cdot}2)=21{\cdot}6$ litres altogether, or 10·8

litres per minute: if for five minutes, 34·2 litres altogether, or 6·8 litres per minute. The reason why he can run faster in a short race than in a long one is that his average rate of expenditure of oxygen can be higher. Now the following table gives the best performances, at various flat distances, of this subject, together with calculations therefrom, on the above assumptions:

Distance.	¼ mile.	⅓ mile.	½ mile.	1 mile.	2 miles.
Time	53 sec.	1 m. 17 s.	2 m. 3 s.	4 m. 45 s.	10 m. 30 s.
Average speed, metres per min.	455	419	392	339	306
Oxygen available in this time (lit.)	17	18·6	21·8	33·1	57·3
Oxygen requirement per min. at this speed (lit.)	19·2	14·5	10·6	7·0	5·5

If, therefore, the maximum rate at which a fit man can run a given distance does depend only upon the amount of oxygen he can obtain (*a*) out of income

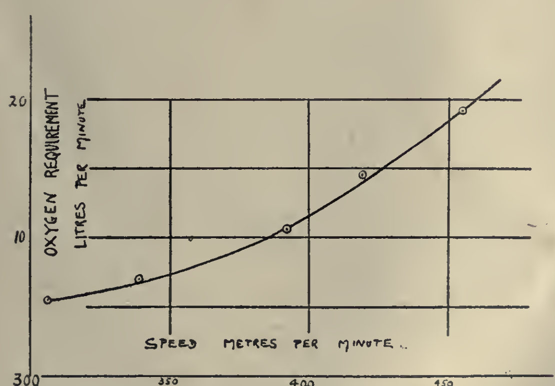

Fig. 4.—Oxygen requirement per minute for running at different speeds: *calculated* from the data in the previous Table.

through the lungs and circulation, and (*b*) on credit, then, knowing the maximum intake and the maximum credit, one can calculate the requirement at the different speeds. Running at 306 metres per minute, apparently about 5·5 litres of oxygen per minute were required; at high speeds much more; at the highest speeds enormously more (Fig. 4).

It is instructive therefore to inquire, by direct experiment, whether the oxygen requirement of running really has the value we have calculated, whether it really rises so rapidly as the speed of running is increased. The oxygen can be measured as before. It is necessary to take into account not only the oxygen actually taken in, but also the increase in the oxygen debt during the period of running. The subject stands at rest and measures his resting oxygen consumption; he runs 100 yards at the required speed; during the run and in the following fifteen minutes his oxygen intake is measured; from this is subtracted the oxygen he would have used had he remained at rest the whole time; the remainder is the oxygen consumption due to the exercise, during and in complete recovery from it. The result is exactly as shown in the figure: the measured oxygen requirement rises continuously as the speed is increased, attaining enormous values at the highest speeds. Hence we may conclude that the maximum time for which an effort of given severity can be maintained is determined mainly by considerations of the oxygen supply, actual or potential, to the active muscles.

Economy of Movement.—This leads us to the important practical question of what is called the "efficiency" of movement. Clearly if a given movement can be carried out more economically, *i.e.* at the expense of less energy, then less oxygen will be required for it, and its maximum duration can be increased. It seems probable that the difference between a good long-distance runner and a bad one may often be due, not to the fact that the good runner has a more effective mechanism for supplying his muscles with oxygen, but rather to the fact that he carries out his movements with greater economy. In any category of muscular effort the unpractised person will use inappropriate muscles and movements, or will use the appropriate muscles with an inappropriate force or rhythm. Some people's nervous systems are naturally athletic: the pictures they form of muscular movement, in terms of the sensations which it gives them, are clear, vivid, and sharp: they realise easily, from its subjective aspects, the most economical, the most effective, and the most convenient manner in which to employ and co-ordinate their various muscles, both in the power, the phase, and the rhythm of their several responses. Other people are clumsy, ineffective, and uneconomical.

If the timing of the valves of a motor, or the timing of the spark, be wrong, or if the valve clearance be not correct, the efficiency drops; so it is in an animal: if the muscles do not react with one another in the right phase, with exactly the requisite force, and in the appropriate rhythm, the movement becomes uneconomical. This economy of effort can, in part, be taught: but just as all the practice in the world will not turn some quite intelligent people into mathematicians, so all the practice in the world may never turn some quite powerful and well-developed people into first-class athletes. Training and practice are essential, but they can only build on an aptitude already there. If a subject use his muscles uneconomically, if—so to speak—the timing and clearance of his valves be wrong, he will need an excessive supply of oxygen. Consequently he will be an ineffective athlete, or an ineffective workman: he is uneconomical. Athletic

prowess depends not only upon a large oxygen supply, but upon a low oxygen requirement.

Mechanical Efficiency.—Finally, let us consider the "mechanical efficiency" of muscular movement in its more technical sense, of work done divided by energy utilised in doing it. The mechanical efficiency of a steam engine may be from 5 per cent. to 20 per cent.: of a gas engine it may be higher, say up to 30 per cent. In man, the mechanical efficiency of muscular movement may be as high as 25 per cent.; the remaining 75 per cent. loss of energy is a serious thing: to what is it due? It seemed, from the purely physico-chemical point of view, that an efficiency of 100 per cent. was conceivable: the free energy of the oxidation of food-stuffs is very large. We know, however, that the body has been organised so that it can go on for a while without sufficient oxygen; it is like an accumulator: it can be discharged and then recharged: it can run into debt for oxygen, and pay off its debt afterwards.

If an animal like man were forced to live within his "oxygen-income," and were able only to make efforts which were possible on his contemporary oxygen supply, he would be a very feeble creature: only about $\frac{1}{4}$th as energetic (for short-lived effort) as he actually is. Moreover, oxidation in the body is a very slow thing; it takes minutes to complete, and it would be a disadvantage to take three minutes over every muscular movement. Hence the mechanism of the muscle has been evolved and differentiated on a different plan: oxidation is not the chemical reaction which directly and immediately provides the mechanical energy of the muscle: the actual process which produces the mechanical energy appears to be some kind of explosive transformation of a glucose di-phosphoric ester into lactic acid, and the subsequent physical or physico-chemical reaction of this lactic acid with the protein structures of the muscle. In recovery the lactic acid is restored, about $\frac{5}{6}$th of it, to the precursor from which it came, the remaining $\frac{1}{6}$th (or its equivalent amount of glycogen) being oxidised to provide the energy for the reversal. Mechanical energy is liberated only in the first stage, which appears to have a very high "efficiency"—probably about 100 per cent. In the recovery stage, however, 150 units of heat are liberated by oxidation for every 100 units in the initial stage, and this reduces the efficiency of the whole cycle to about 100/250, *i.e.* to about 40 per cent. Apparently, therefore, a big reduction in efficiency is effected simply by taking proper account of the recovery process, and is due to the need the animal often experiences of taking violent exercise, so to speak, "on credit."

Even so, however, 40 per cent is far higher than the efficiency actually found in man: the remaining reduction of efficiency is due to two other factors: (*a*) to the rapidity of the usual type of muscular movement, and to consequent frictional loss inside the muscle; and (*b*) to the physiological effort associated with *maintaining* a contraction.

With regard to (*a*), muscle is made up of a viscous material, not unlike egg-white or treacle, with a fine network of membranes, fibres, and tubes throughout it: the joints, the tendons, the connective tissue, the blood-vessels and the blood within them, are similarly of a viscous nature. Now, when a viscous fluid is forced to flow, mechanical energy is wasted and turned into heat: the faster it is made to flow, the more energy is degraded. But when a muscle changes its form, and produces a movement in a limb, the tissues have all to fall into a new form, viscous fluid has to flow into a new disposition, energy is degraded into heat: and in the more rapid movement we should expect more energy to be wasted. Experiment amply confirms this expectation: the frictional loss is greater, the greater be the speed of movement. This explains why it is so laborious to pedal a bicycle on too low a gear, and why very rapid running requires such an enormous amount of energy. In both cases the external resistance may be small or negligible. The internal resistance, however, is large, and increases directly as the speed of movement, until finally a limit is reached at which no further increase in speed is possible; every muscle fibre is then working to its physiological limit of speed and power, merely in overcoming its own internal resistance.

With regard to (*b*), just as it is inefficient and tiring to move our limbs too rapidly, or on too low a gear, so also it is inefficient and tiring to move them too slowly, or on too high a gear. This simple observation gives us the clue to the third and final reason why the efficiency of muscular contraction is relatively so low; a contraction which continues too long requires energy to maintain it, as well as energy to set it up, and from the point of view of doing external work the *maintenance* of contraction is ineffective. Experiments were made in which the heat produced by a muscle was determined as a function of the duration of the stimulus exciting its contraction. After an initial outburst of energy associated with setting up the contraction, the heat-production increases uniformly as the duration of the stimulus is increased. Hence we see why slow and prolonged movements are inefficient: a large and unnecessary part of the energy is used in maintaining the contraction. This is the phenomenon we all know in our own bodies: to attempt to lift a thing which is too heavy for us to move is more tiring than actually to lift a thing we can move, even though no work at all—in the mechanical sense—be done in the former case.

Labour and the Universities.

THE subject of "Labour and the Universities" was included in the agenda of the annual conference of the Universities of Great Britain and Ireland held in London on May 13. Mr. Arthur Greenwood, M.P., who opened the discussion, said that the Trade Union, Co-operative, and other working-class movements needed in an increasing measure trained men with the broad outlook and the other qualities which a university education could give; but he did not believe they were getting a fair share of the existing resources. This defines one part of the problem of Labour in relation to the universities in the simplest and clearest language. Admittedly the problem is not yet solved: but, as Prof. Elton of the University of Liverpool said, there is a disposition on the part of the universities to do all that can be done to find the solution. He invited Mr. Greenwood and his friends to tell the universities plainly what they wanted, coupling the invitation with a hint that the Labour Party must not expect the teaching of such subjects as economics and history to be adapted to the political tenets of their party. "Some sections of Labour," Prof. Elton said, "suspected that university economics might be capitalistic economics, and that history might be some form of Imperial history"—a suspicion which he believed to be unfounded.

One other warning might have been added. The educated man is not created *per saltum*: he is the product of years of toil, sacrifice, dedication. It may be true, as Mr. Greenwood said, that knowledge and an enthusiasm for knowledge would give the working classes something which no trade depression could take away. But how much study would this require? With the rapid advance of knowledge in all subjects, the problem of education becomes more and more complex for everybody, but especially for those who, under our present social system, are obliged to devote most of their time to forms of labour which are remunerative only in a physical sense. Prof. Burnet, in his recent Romanes lecture, warned us that specialism, pushed to its logical conclusion, would land us in a society where no one knew anything that any one else knew. There is real danger that working men may look with indifference on the Mount Everest of science. It is fair to say, however, that the higher education of the working classes, as directed and inspired by the Workers' Educational Association, has shown a disposition to encourage the thorough and humane study of a relatively small field in a spirit which gives to the student not only

knowledge of facts but wisdom to understand and interpret:

> "Knowledge is proud that he has learned so much;
> Wisdom is humble that he knows no more."

If, as we hope, there is no confusion of ideals in regard to the higher education of the working classes, questions of method and machinery should not present insuperable difficulties. The needs of the adolescent are, in many respects, distinct from those of the adult. Representatives of the Labour Party have often contended that there is at present in the youth of the working classes a great "stream of talent" which is allowed to run to waste. This contention has never been fully proved; but if it is true, the blame must rest with the Board of Education and the local education authorities for neglecting their statutory duties. As to the adult, the tutorial class and summer course are methods which have stood the test and yielded good results. The Master of Balliol, in a paper read at the conference, said that the summer school required to be better organised and more developed. Sixteen years' experience had shown what potentialities were in that direction. Another possibility was the organisation of one-year courses of intensive study in universities for selected extra-mural students so that adult education might breed its own teachers. Finally, he suggested, there was a need to develop the system of resident tutors in districts—"decentralised university work."

So much on the question of what the universities can do for Labour. There remains the converse question—what the Labour Party can do for the universities?—a question which has assumed greater importance since the Labour Party became His Majesty's Opposition. It is gratifying that the Labour Party, alone of the great political parties, has made the question of university education the subject of formal investigation and study. Their memorandum of evidence submitted to the Royal Commission on Oxford and Cambridge Universities, and recently published in the Appendices to the Report, gives proof of an earnest desire to make our ancient universities more efficient in a national sense. The memorandum is unsigned, and it is therefore difficult to determine its final authority. It speaks throughout, somewhat oracularly at times, in the name of the Party. Occasionally, however, the views expressed appear to have a personal character. For example, can it be supposed that the average member of the Labour Party, whether a horny-handed son of toil or one of the so-called "intellectuals," feels with any intensity of conviction that "the old Pass course both at Oxford and Cambridge should be abolished"?

There is much to be said for the view that specialisation has been carried too far in university education and that, for teachers particularly, a broader course of study than is at present offered by the Honours schools is to be preferred. In the United States, the first degree is granted on a general course of training, specialisation being postponed to a later age. Proposals to introduce "honours" degrees on the English pattern have been vigorously resisted in America on the ground that it is undemocratic to label some citizens as intellectually superior to others. Should not these questions of curricula be settled by educational experts rather than by work-a-day politicians?

The control of the universities which receive financial aid from the State is on a different footing. The memorandum states that "the Labour Party does not wish to deprive the universities of their independence; on the contrary, it would encourage their initiative within the national educational system"; but it goes on to assert that "something of the nature of continuous administrative control by the State must be undertaken." Thus are our universities to be placed on the slippery slope which leads to intellectual regimentation. Questions of new developments in literary and scientific research in universities will have to be submitted to Government officials as are, under present arrangements, questions of supplies for elementary schools.

No doubt co-operation and co-ordination could be carried further in university education, and the Government might stimulate the self-activity of the universities in these matters. But the doctrine of continuous administrative control is fraught with danger. Mr. Wood, the president of the Board of Education, speaking at the conference, admitted this. "In my judgment," he said, "if the universities are to fulfil their functions and duties, it is vital that they should retain the fullest measure of liberty possible. There is at present no disposition to challenge that principle. So long as the universities can justify the work that they are doing, so long, I think, Parliament will be prepared to trust the universities to do it."

Psycho-analysis.

(1) THE physician who makes acquaintance with psycho-analysis in this, the first of Dr. Stekel's clinical works to be translated, will assuredly experience some kind of emotional reaction. The author takes for granted that therapeutic aims should not be hindered by reticence or taboo, but although medical men have accepted that principle in regard to the anatomy and physiology of sex, yet its application to the psychological factors is, in the form presented by Dr. Stekel, so thoroughgoing as to arouse certain opposition. The reader may capitulate in face of the mass of clinical evidence, or find in the frequent and facile dogmatism of the author a reason for rejecting whatever appears strange or new. The statement, for example, that "the sex impulse may be directly identified with the instinct of self-preservation" (page 3) is presented with no evidence or explanation, and we are left to guess whether it is a tenet of psycho-analytical orthodoxy or one of Dr. Stekel's own bright thoughts.

The many blemishes of this nature are unfortunate, for the book fills a gap in medical literature by its detailed accounts of the bodily symptoms of the anxiety states, symptoms which are commonly treated from the physical point of view with a total neglect of the underlying mental condition. Heart and stomach neuroses, asthmatic attacks, even the anxiety attack itself, rarely meet correct recognition, and Dr. Stekel gives clinical examples of all these with the mental factors fully analysed; a host of other disorders—phobias, professional neuroses, stammering, and the like—are adequately illustrated. The psychical treatment of epilepsy is approached with commendable caution, but the enthusiasm and confidence with which the author handles the therapeutics of melancholia are not shared by his analytical colleagues.

The book is a blend of useful information with rash dogma. The translation shows many literal errors and should have been revised by some one acquainted with medical terminology.

(2) Dr. Pfister combines the functions of pastor, pedagogue, and psycho-analyst, and his writings are regarded by psycho-analysts as serious contributions to their subject. In his opening essay he tilts at orthodox psychology, which certainly has failed to render to medicine or education the service that psycho-analysis offers, but in Great Britain at least the "psychology of the schools" no longer refuses to admit, however grudgingly, the importance of Freudian fundamentals. Pfister quotes from Stern the advice to differentiate between the actually perceived external fact and the interpretation attached to it. Psycho-analysts sometimes offend against this self-evident maxim in one direction, and their critics, on the other hand, often insist upon treating observations as if they were interpretative artefacts; it is notable that Pfister makes clear in his analyses what are the patient's associations—the perceived facts—and what are the interpretations.

Pfister's analysis of an artist and his art serves the double purpose of illustrating technique and studying the psychological processes of artistic inspiration, which is the manifestation of repressed desires and comes into line with neurotic symptoms and dreams, except that an ingenious whole is created. The latent significance of a picture is for the artist, the manifest is for others, but may not the success of an artistic production depend upon an unconscious appreciation, on the part of beholders, of the latent significance? In the chapter on "Psycho-analysis and Philosophy" Pfister acclaims Freud as the first great positivist among psychologists, but makes a plea for metaphysics as a stage towards the highest plane of knowledge. Of more immediate interest is the relation of analysis to ethics, for, as the author points out, the most powerful argument of Freud's opponents is that his procedure is immoral. Ethics, he says, is an empirical science standing in need of purely objective and sober criticism (p. 299), and "all ethics which ascribe to experience an influence upon its standards (and another kind of ethics is scarcely conceivable nowadays) may derive the most important doctrines from these discoveries" (p. 195).

Educationally, psycho-analysis aids more in the removal of inhibitions than in the prescription of methods, and the chapter on "Child Life" is the most

useful in the book; it gives accounts of actual cases which show that the analytic method of approach is the most hopeful one for the understanding and treatment of the "neurotic" child.

There is a want of correlation between the different essays, and it is doubtful whether a reader new to the subject would find it made sufficiently clear: yet the book is useful to place in the hands of people who see only evil in psycho-analysis.

(3) It is not realised that Freud and Jung, starting with a general agreement upon observed material, have so far diverged that Dr. MacCurdy expresses the usual Freudian view when he writes "No attempt has been made to consider the theories of Jung because, quite frankly, I cannot understand them" (p. xiii of "Problems in Dynamic Psychology"). Yet, although Jung admits that his earlier book ("Psychology of the Unconscious") so aggravated the difficulty that "many otherwise able minds became utterly confounded" (p. 626), this book concerns practical psychology in a sphere where Freud offers little help. Psychological types have always been recognised: William James defined the tough-minded and the tender-minded, or the rationalist and the empiricist, and found the history of philosophy to be mainly that of a clash of temperament. Furneaux Jordan (whose work with Herbert Page on "Railway Spine" is a neglected but important chapter in psychological medicine) is credited by Jung as being the first to give a relatively appropriate characterisation of emotional types. Jung himself has already developed the ideas of introversion and extraversion as character types, and in actual life the want of *rapport* between these types is a matter of daily observation. He notes "the normal bias of the extraverted attitude against the nature of the introvert" (p. 472). A recent novel attained success with its picture of the dis-harmony between the introverted Mark Sabre and his extraverted wife, and whoever ventured to criticise the hero inevitably revealed, by the nature of his criticism, the nature of his own type.

Jung now carries his analyses of types to a finer degree of differentiation, according as they are marked by excess of feeling, thinking, sensation, or intuition. His description is often practical and understandable; the extraverted intuitive type, for example, to which commonly belong merchants, contractors, speculators, agents, politicians, etc., is to be recognised in actual life, and, though he makes no mention of the application, a knowledge of the different types in children should be a useful part of the pedagogic art. But his discussion of the type problem contains a good deal of what will appear to many readers as mysticism. His conclusion is that each type views psychic processes in a manner peculiar to that type; that every theory of the psychic processes is in its turn a psychic process; hence every individual supposes that there is only one interpretation of the psychic process, namely that which agrees with his type. "The scientific theorist is confronted with the disagreeable dilemma of either allowing mutually contradictory theories of the same process to exist side by side, or of making an attempt that is doomed from the onset to found a sect which claims for itself the only correct method and the only true theory" (p. 627). Whether one rests content with this conclusion is a matter of one's own psychological type.

(4) Dr. Rivers's mode of thought was so remote from the rationalisations of politics that it was not easy to imagine him in the political world; his candidature was only possible in the comparative calm of a university constituency, and these essays, as Prof. Elliot Smith says in his prefatory note, were a most remarkable form of appeal to parliamentary electors. It seems likely that as electoral propaganda they would have met with only moderate success; a serious study of "red-tape" as "an attitude which must be understood if we are to correct the evils now associated with government control," for example, lacks the emotional appeal of vituperation, and even in an educated constituency the belief in the intellectual power of political ideas is so strong that few voters would be attracted by the view that "no great movement is likely to succeed except under the leadership of one who is able to inspire a degree of confidence comparable with that which actuates the instinctive attitude of the animal herd towards its leader." In fact, Dr. Rivers's demonstration of the strength of the instinctive and unwitting motives in political and social life indicates the tactical weakness of his own unemotional and logical presentations. Nevertheless, those who turn away from the catch-words and pseudo-intellectualism of politics will find pleasure in these essays while regretting that the voice was that of one crying in the wilderness. Dr. C. S. Myers writes an appreciation of the work of the late Dr. Rivers, which expresses the feelings of all who knew him.

(5) In the opening lines of his preface Prof. Elliot Smith tells us that "The aim of this book is to give a sane interpretation of the significance of dreams . . ." and the implied criticism of other interpretations does not prepare us for the absence of emotion or prejudice that marks this posthumous work of Dr. Rivers. Accepting the truth of the main lines of the Freudian position, Dr. Rivers examined his own dreams by encouraging a half-sleeping state in which the thoughts came which furnished the explanation of the dream. Working also with the dreams of patients, he tentatively propounded certain views as alternatives to

those of Freud. Instead of a wish-fulfilment he regarded the aim of the dream as an attempt at the solution of a problem, generally associated with a current difficulty, while he ascribes the form of the dream to a regression to modes of activity characteristic of early life instead of to the influence of early desires. These differences are not of vital import; in fact, on page 98 reference is made to dreams and their analyses recorded by Freud himself, in which Dr. Rivers found a striking similarity with respect to the recency of the conflicts they reveal, and he suggested that the dreams of a patient under analysis may be influenced by the attention of the dreamer being led back to the experience of early life.

Dr. Rivers doubted the scientific value of free association as a means of leading back to the source of the dream, though there may be clinical value in the material thus obtained. Pfister, in the book reviewed above, admits this doubt when he writes (p. 38): "We do not by any means believe that *every* association . . . shows the paths by which the image under investigation was produced." Freud's conception of the "censor" is rejected in favour of the supposition that as sleep becomes deeper the dream takes on a more infantile mode of mental activity and hence is more disguised and more readily forgotten. In regard to the universality of symbolism Dr. Rivers was in more serious discord with psycho-analysts. By "universality" he did not mean the invariability of the symbolic meanings, for the existence of such invariability is not claimed; it *is* claimed, however, that certain symbolisms are innate and universal to all mankind, and this claim Dr. Rivers denied on ethnological grounds.

This book, with that of Dr. MacCurdy, should be welcomed by psycho-analysts. The vigour of the heresy hunt is now abating, but, more than from the intimidatory effect of the hunt, psycho-analysis has suffered from the absence of scientific criticism. The death of Dr. Rivers has meant the loss of one of its few understanding critics.

(6) Dr. MacCurdy assumes that his readers know and accept the observations of psycho-analysts, which he confirms from his studies of the psychoses, but when he examines Freud's theoretical principles he finds them, to his surprise, not internally consistent. He meets difficulty in Freud's conception of the ego and its relation to the libido and finds untenable the idea of the object libido being transformed into ego libido, while he rejects as arbitrary and unconfirmed Freud's pathology of dementia precox as a withdrawal of the libido from the outer world with a transformation into ego libido. He is content to regard the disease as marked by a central theme, often of a crude Œdipus order, and the problem is how such a theme can gain this ascendancy. English psychiatrists will perhaps be surprised at the entire neglect of the pathological findings in this disorder, but the physiological and psychological points of view seem to be mutually exclusive.

It is characteristic of Dr. MacCurdy's position that he criticises Freud's theories from a point of view that demands attention from Freudian orthodoxy, which has been compelled to ignore the criticism of those who without investigation dismiss the findings of analysis as absurd and void of psychic reality. In the case of the war neuroses, to quote a simple example, the use of an easy technique demonstrated the existence of buried memories that expressed themselves in the bizarre symptoms of shell-shock, but discussion was impossible with objectors who refused to acquire the technique necessary to confirm or confute the observations. Similarly the significance of the birth-phantasy—a common-place finding of analysis—has not hitherto been subjected to useful criticism. But Dr. MacCurdy rejects as a wild speculation the idea that unpleasant feelings at birth have become the prototype of anxiety and are repeated in states of anxiety (it is curious that the same hypothesis was propounded by Erasmus Darwin in "Zoonomia"); he agrees that mythology, delusions, and dreams are replete with examples of birth experience, but points out that the unconscious ideas of painful birth may originate in later life and have psychic reality without being memories at all. He agrees, too, that each analyst finds what he is looking for, but declares this a matter not of suggestion but of selection, and believes that even with this partial selection cure results as soon as sufficient unconscious energy is deflected from symptoms to constructive activities. A chapter is given to an appreciative but critical examination of the theories of Dr. Rivers.

This important book is constructive as well as critical, and ends with a consideration of the co-operation and conflict of instincts and the statements—in which psycho-analysis takes the offensive—that "Ego and sex instincts, when in the ascendant, lead to the destruction or ineffectiveness of the individual," but "The world of men suffers and has suffered more from . . . insensate devotion to the herd than from all crime, insanity, or nervousness."

Millais Culpin.

Chinese Potters and Porcelain.

The Wares of the Ming Dynasty. By R. L. Hobson. Pp. xvi+240+59 plates. (London: Benn Bros., Ltd., 1923.) 84*s*. net.

This admirable account of the arts and crafts of the Chinese potters and porcelain-makers during those spacious days of its history when the Celestial

Emperors held sway over the larger part of eastern and central Asia is worthy of its great subject; and one could not award it higher praise. The position of Chinese porcelain is so commanding in the history of man's art and craftsmanship, and its example and influence have proved so dominant in Europe, as well as in the Far East, that so comprehensive and reasoned a survey of its development will prove of signal interest to all lovers of fine and noble porcelains; whether their predominant interest is centred in the wares of Asia or in those, of later date, that have been made in Europe. Only an untiring student and scholar, who has charge of a famous collection such as that in the British Museum, and who has worked, there and elsewhere, at the subject in all its aspects, could have produced a volume of such sterling worth. All available sources of information have been utilised—the accounts of early European travellers are drawn upon equally with the latest records of exploration and research—so that we are here presented with as trustworthy an exposition of the subject as we are likely to obtain, and one which might well serve as a model for later workers in similar fields.

It is refreshing and gratifying to find such an authority as Mr. Hobson dealing so outspokenly with some of the common misconceptions cherished by many dealers and collectors. "Misconceptions about Ming are so many, and the word has been so frequently abused, that it will be well to devote a little destructive criticism to the things which are not Ming, but too often masquerade as such. . . . Ming is not a home for stray pots, in which every mongrel piece, which has no fixed attribution, can find a refuge. . . . Not long ago all glazed pottery figures were called Ming as a matter of course. No self-respecting merchant would have thought of stocking anything later in that line of goods, . . . etc." These are but two examples of many that might be cited where Mr. Hobson, as befits his position, has performed a real service to students and collectors alike; but many such illuminating *dicta* occur throughout the work, and it is encouraging to find valuable advice and information conveyed in such an authoritative and unhesitating a fashion.

Two special chapters are devoted to a consideration of Ming technical methods, and they have been compiled in such a way as to provide a sound and trustworthy foundation on which the collector may base his own knowledge. In addition to a clear and succinct account of the raw materials used in the body and glazes and the regions whence they were obtained, there is a description of how the more important varieties of porcelain were fashioned, finished, painted, and fired. The subdivision of labour "which effectually obliterated the individuality of the decorators" is explained, as well as the fact that the painted designs were mostly based on well-known paintings and on such standard patterns as those used in silk-brocades. These had been filtered through the hands of the Palace artists, whose designs were sent to Ching-tê Chên to be copied on the ware by the porcelain decorators.

As an example of concise statement it would be difficult to surpass Mr. Hobson's account of the method by which gold was applied to the Ming porcelains. "Gilding was used from the earliest reigns of the Ming. It was the last operation in the manufacture and always required a separate firing at a low temperature. Thus one of the red bowls described will be fired first in the full heat to take the body and glaze and develop the underglaze blue inside the bowl, then it would have the outside covered with red enamel which had to be fixed in the muffle stove; and finally the gilt floral pattern would be painted over this red and fixed by another visit to the muffle. In several cases the gilding on these red bowls is applied in the form of gold leaf, while in others it was evidently painted on with a brush."

Space will not permit me to dwell further on the merits of the work, but attention must be directed to the excellence of the numerous illustrations and the selective skill with which objects have been chosen to cover, adequately, such an extensive field. The coloured plates are of remarkable excellence; the subtlety of the Chia Ching bowl decorated with enamel colours (plate 7) being as perfectly suggested as is the precision of the design of an earlier type, in a more conventional style, which appears as the frontispiece. The half-tone plates are equally successful, and as the objects chosen are often of extreme beauty, they undoubtedly add to the value and distinction of the book.

WILLIAM BURTON.

Maps and Survey.

Maps and Survey. By Arthur R. Hinks. Second edition. Pp. xvi+258+26 plates. (Cambridge: At the University Press, 1923.) 12s. 6d. net.

THIS new and enlarged edition of Mr. Hinks's book is heartily to be welcomed, for it forms an admirable introduction to the whole subject of map-making, both in the field and in the office. Indeed, in some respects, it is more than an introduction, for such chapters as "Maps and Survey in War" and "New Methods of Survey" can be read with advantage even by those experienced in the construction of maps. An excellent feature of the book is its wide outlook; thus examples are given of methods of work and of instruments used, in the United States, in France, in India, and in the British Protectorates and Colonies,

as well as those employed by the Ordnance Survey and in British military practice at home.

In his preface to the second edition the author states that it should be considered as transitional from the pre-War subject which he taught in the geography school at Cambridge "to the considerably developed and altered maps and survey" which have come within his experience at the Royal Geographical Society. It is a fact that not only has the subject altered considerably in recent years under normal conditions, but also the War has brought forcibly to the attention of surveyors the great value, in suitable circumstances, of air-photo-surveying and of photographic methods generally; while in peace-time exploration the use of wireless time signals for the determination of longitude has removed the traveller's greatest technical difficulty.

An interesting addition is entitled "A further Chapter on Maps"; it deals with some of the many problems which are now before the cartographer, such as flying maps, the international air map, the spelling of place names, and styles of lettering. As an example of the difficulty of meeting the airman's requirements it is pointed out that, on the international air map, the sign for Brest must indicate aerodrome, sea-plane station, wireless, radio-goniometer, wireless telephone, meteorological station, aerial light and aerial ground-sign: a striking example of the difficulty of selecting conventional signs. While dealing with the subject of conventional signs it may be mentioned that the Ministry of Transport and the Ordnance Survey are now publishing a new set of half-inch maps of Great Britain, giving the new road classification and the road numbers approved by that Ministry. The issue of this series of maps has taken place since the book under review was published. The chapter ends with an analysis of more than thirty new types of maps, mostly published since the first edition of this book was printed.

The account of maps and survey in war is excellent, and is chiefly based on the experience of the British Army on the Western Front. Some of our cartographic difficulties were caused by using a grid marked in squares of a thousand yards' side printed over maps, with dimensions derived from the Belgian Survey, which were a definite number of kilometres in length and depth. Then as regards the projection, both French and Belgian peace-time maps were plotted on Bonne's projection, which gives equivalence of areas but is not well suited for military use. Both English and French survey staffs came to the conclusion that it was desirable to adopt a form of orthomorphic projection, and the French in 1917 introduced a close approximation to Lambert's conical orthomorphic projection. Arrangements had been made for the British to follow suit, when the War came to an end. Of course the quality of orthomorphism only strictly holds locally, but for some miles it is sensibly exact. These questions of the grid and projection have their importance, but it would be wrong to overestimate it. Generally speaking, the British maps on the Western Front were excellent, and compared most favourably with those of the enemy; and it was undoubtedly right to start with the Belgian projection and size of sheet—in no other way could the maps have been produced in time to be of use in the early days of trench warfare.

The book ends with an account of photo-stereoscopic survey, including a description of the stereo-autograph of von Orel—of the Military Geographical Institute of Vienna—another instance of the debt which the arts of surveying and cartography owe to the armies. This stereoscopic method has a future before it, but at present the price of a von Orel machine is high, and it is to be hoped that some less costly and less elaborate piece of apparatus may be devised which will be equally efficient. As the author remarks, however, the method is not easily applied to flat country without commanding points of view, and is not suitable for very small scales.

It will be seen that Mr. Hinks's book is in effect an excellent account of the present state of surveying and cartography, and all interested in these subjects will find the book well worth perusal and study.

C. F. C.

The Drapers' Company and Statistical Research.

Department of Applied Statistics, University of London, University College. Drapers' Company Research Memoirs. Studies in National Deterioration. IV.: On the Relationship of Health to the Psychical and Physical Characters in School Children. By Prof. Karl Pearson. Pp. 77. (London: Cambridge University Press, 1923.) 15*s*.

IN this most recent of the Drapers' Company Research Memoirs Prof. Karl Pearson discusses the relationship of health to the psychical and physical characters of school children, on the basis of information supplied by selected schoolmasters and schoolmistresses, some years ago, in respect of more than 2000 boys and 2000 girls in schools for the professional classes. The information represents, as it were, the collective considered and recorded judgment of the masters and mistresses who contributed, and previous examinations of the data have afforded evidence of trustworthiness. Prof. Pearson finds that the statistics show little relationship between health and the characters considered: the healthy

child is rather more intelligent, vivacious, and self-assertive and considerably more athletic than the less healthy, but the physical characters (head measurements, hair, eye colour, etc.) show no relation on which stress could be laid. In the course of the work the author sums up in general terms what the statistics show to be the athletic and the popular child. The latter is intelligent, conscientious, athletic, healthy and good-natured or quick-tempered rather than sullen: self-assertive children are a little less popular than the shy. Red-haired boys and wavy-haired girls enjoy a large share of popularity but in other respects appearance seems unimportant. The athletic child may be summed up as a "healthy, reasonably intelligent, and fairly conscientious, if somewhat self-assertive and undoubtedly noisy child who is quick-tempered, but not sullen . . . in several respects better, in none worse, than the average child."

No one will, in all probability, cavil at these results, but Prof. Pearson before reaching them had to examine the effect of age on the various characters, and in this part of his work he comes to conclusions which, he seems to think, will find less ready acceptance. These conclusions are that general intelligence and a variety of psychical characters seem to be unchanged throughout school life, that general health changes exceedingly little during the same period and the statistics do not support the "widely-spread opinion that Health is a governing factor of temperament." Our surprise is not so much at the results as at the expectation of disagreement. As general intelligence is described as a measure of capacity and not of acquired knowledge, the teacher's work is, in a sense, eliminated from the calculation, and surely any masters or mistresses may feel satisfied if school influence teaches control of temper although it cannot make the quick-tempered child into an even-tempered one. The author's analogy is to the point: you will need to harden, temper, and grind your chisel if it is to become efficient for its task, but no amount of treatment will permanently convert bad steel into good steel. With regard to the conclusion that general health changes little with age, this might have been anticipated, because rates of mortality and sickness increase but little with the age during the years of school life, and the "widely-spread opinion" to which reference is made by Prof. Pearson is perhaps the outcome of a kindly wish to make excuses for the temperamental shortcomings of an unhealthy person. But, after all, the only practical way of reaching conclusions on such matters is by collecting evidence from samples of the population as Prof. Pearson has done, and the conclusions so reached are preferable to those general impressions on which people form their opinions regardless of the fact that few of us take account of all the cases that pass before us, but are tempted to rely on the relatively small part of the experience, which by its rarity rather than its frequency creates an impression.

The Memoir was prepared as a lecture, and while giving a careful discussion of the statistical problems, etc., it contains remarks intended to make it attractive to a listener: these lighter touches make it easier, but no less pleasant reading than some of the more severely mathematical work that has been published in the same series.

This brings us to another aspect of the Memoir to which we may direct attention. It is the latest of a very large number of productions that bear the name of the Drapers' Company. For twenty years or so, papers have been written and issued from University College with the help of this Company. The Memoirs include much original work on the theory of statistics; the three volumes on albinism with which Nettleship and Usher were largely concerned—a storehouse of information—monographs on anthropometric subjects, many technical papers, studies in fertility and disease, and, in some respects as important as any of these, the tracts for computers and the volume of tables for statisticians. It would have been a great output for the period for any department—even if its other activities were ignored—but it would have been an impossibility if there had been no financial help available. The Drapers' Company has helped science in other ways, and it must be gratifying to such generous givers to see the help used to so good a purpose, and to know, as surely the Company must, that its gift is appreciated, for the help it affords to scientific research, by many people besides those connected with the Department or the College to which the grant is actually made.

Our Bookshelf.

Hutchinson's Splendour of the Heavens: a Popular Authoritative Astronomy. Edited by T. E. R. Phillips. (In about 24 Fortnightly Parts.) Part 1. Pp. 48. Part 2. Pp. 49-88. Part 3. Pp. 89-128. (London: Hutchinson and Co., 1923.) 1*s.* 3*d.* net each part.

THE name of the editor of this serial, the secretary of the Royal Astronomical Society, is a sufficient guarantee of the excellence of the work. As collaborators he has gathered together a band of observing members of the Society, each an expert in one or other of the subjects which will constitute the work. The salient feature of the parts which have appeared is the beauty of the plates and of the illustrations which are scattered so lavishly over their pages. Sources both ancient and modern have contributed a veritable picture gallery of the science. This will appeal to both young and old, to the student, and not less to the adept.

The descriptive matter too is not unworthy of the pictures. The writing is popular in the best sense of the term, simple, but yet exact in the exposition of the fundamental laws and the progress of observation of the physical facts of the science. The explanations are rendered more intelligible by apposite and original diagrams. After a general and historical introduction by the editor, Dr. Steavenson treats of the "Story of Light and Man's Control of It," with illustrations of telescopes from that of Galileo to the giant 100-inch reflector at Mount Wilson. Spectroscopy is adequately explained, and the chapter concludes with an account of the astronomical applications of the interferometer. Of Chapter II. "The Solar System," it is enough to say that it is in the very capable hands of Dr. Crommelin. It is a model of popular scientific style. "The Sun and Sun-spots" constitute Chapter III., written too in a fascinating manner by Mrs. Maunder, and copiously illustrated by very fine photographs, mainly from Greenwich Observatory. Mr. C. P. Butler writes on the "Prominences," and the stars and nebulæ, meteors and comets, gravitation and tides are among the subjects yet to be discussed.

The title "The Splendour of the Heavens" is well chosen, for it is this aspect of the firmament which excites wonder and appeals most directly to the mind of man. It inevitably leads to the recognition of the Majesty, the Wisdom, the Beauty of the Creator, and is thus an antidote to the naturalism, and to the stark materialism which is the bane of much of modern science. With unstinted praise we can recommend this excellent serial, which promises to be a standard work of popular astronomy. A. L. C.

Guide to the Mollusca exhibited in the Zoological Department, British Museum (Natural History). Pp. 55. (London: British Museum (Natural History), 1923.) 1*s.*

A NEW edition of the Guide to the Mollusca in the British Museum (Natural History) has been certainly long overdue, none having been issued since 1908, when other Invertebrata were associated with the Mollusca in the descriptive account of the "Shell and Starfish Galleries."

This new Guide occupies practically the same number of pages as did the section of 1908, although much of it has been rewritten, and in its "get up" is fully equal to others of its kind for which the Natural History Museum is famous. It cannot be exactly described as a "popular guide"; the subject does not lend itself to that, as the mammals and birds do, but it appeals rather to more advanced students of the particular subject. The casual visitor desirous of more simple explanation can fortunately rely on obtaining the information he may require from the demonstrations of the Official Guide, who alone probably can satisfactorily deal with such. No one who has not attempted a similar production knows how difficult it is to produce a really satisfactory work of the kind, or of the pitfalls that beset the compiler, to whose own lapses may be added those introduced by the "familiar" of the printing press.

Beyond pointing out that the scientific name of the British freshwater pearl mussel has somehow been applied to the marine pearl oyster of commerce (Pinctada), we do not propose to dwell on those errors we have observed, preferring to leave that task to "kind friends." It is a pity, however, that further currency has been given to a text-book statement that a "*Helix* has been known to survive a temperature of $-120°$ C." and even to have strengthened the startling statement by substituting "tolerate" for "survive." We suggest a lost decimal point as explanation.

Physikalische Chemie der Zelle und der Gewebe. Von Prof. Dr. Höber. Fünfte, neubearbeitete Auflage. 1 Hälfte. Pp. xv + 544. (Leipzig: W. Engelmann, 1922.) 575 marks.

THE late Prof. Benjamin Moore reviewed this important book at length in NATURE (November 30, 1911, vol. 88, p. 140) upon the appearance of the third edition. The general character of the book is unaltered in this the fifth edition, and it still remains one of the outstanding texts for the use of students of physiology.

The present edition has evidently been completely revised, the most striking modification being the division of the book into two main sections; the first dealing with the underlying physico-chemical phenomena apart from their manifestation in the living organism, the second part considering the operation of these phenomena in living cells and tissues. The book also now appears in two volumes; this first volume includes the six chapters comprising the first section of the book, while Chapter VII., the first chapter of the second section, discusses the osmotic properties of cells and tissues. The material of this seventh chapter in the third edition appeared scattered throughout three chapters dealing respectively with osmotic pressure, osmotic properties of cells and tissues, and a criticism of the lipoid theory. Judging by the present volume, the rearrangement of the subject-matter has provided a more natural and logical presentation of the subject. It is also certainly natural to find that a discussion of permeability no longer centres around the lipoid theory of the plasma membrane. Throughout the book modifications have been made in accordance with the trend of modern physiological investigation; to cite one example, Chapter III., upon the quantitative estimation of hydrogen ions, has been altered to cover the modern use of a wide series of indicators in conjunction with standard buffer solutions; it also includes a fuller discussion of the regulatory mechanism controlling the reaction of the blood.

English Coastal Evolution. By E. M. Ward. Pp. xii + 262 + 14 plates. (London: Methuen and Co., Ltd., 1922.) 8*s.* 6*d.* net.

MR. WARD has chosen a very interesting subject, and has treated it systematically and well. In his general introduction, he points out that the present features of our coasts are built up or carved out on a land that has been recently submerged. The features of this land are largely due to subaerial erosion, but in places they are becoming modified by the deposits caught on sea-worn flats. In other places features are becoming again revealed by the removal of beach-detritus belonging to an earlier epoch. The glacial deposits that extended the land-area as the ice melted away form here and there protective

barriers, but have little stability against the battery of the waves. The pictures of coastal "planes of marine denudation" (Ramsay wrote "plains" for his larger features) are pleasing examples of the many excellent photographic illustrations.

The English and Welsh coasts are dealt with by districts, which is a far better method than any attempt to distinguish coasts of accumulation from those where erosion is now active. The descriptions thus appeal to readers who know the landscapes, and they add much in the way of local geography for dwellers near our shores. The descriptions of the Chesil Beach and the coves of the Dorset coast may be cited as examples of this treatment. Note has been taken of the probable derivation of the big stones of the Chesil Beach from flint-gravels formed on lost but adjacent land. The re-opening of Pagham Harbour in the Selsea area by a heavy gale in 1910 provides a parallel on a small scale with the flooding of the lands west of Dordrecht in 1421. The loss and gain of land in East Anglia is illustrated by many details and references that show the wide reading of the author.

This readable book forms a sound basis from which a historian might proceed to a study of our maritime industries, our relations with the continent, and our great adventures overseas. G. A. J. C.

The Statesman's Year Book: Statistical and Historical Annual of the States of the World for the Year 1923. Edited by Sir John Scott Keltie and Dr. M. Epstein. Sixtieth Annual Publication: Revised after Official Returns. Pp. xxxii + 1583. (London: Macmillan and Co., Ltd., 1923.) 20*s.* net.

THE sixtieth issue of this well-known work of reference shows the same high degree of accuracy for which previous issues have been distinguished. The information for every country for which statistics are available has been carefully revised, and the same applies to the full lists of works of reference dealing with every part of the world. For the first time Turkey appears shorn of its old-time possessions, which now figure either as independent states or as mandated territories of other states. The new conditions in Ireland have resulted in two new sections devoted respectively to Northern Ireland and the Irish Free State. In default of separate figures, certain statistical information for Ireland has still to be included under Great Britain and Northern Ireland. The term United Kingdom would seem to have disappeared. The two coloured maps in this issue show respectively Ireland, and Palestine with Trans-Jordan. There are the usual statistical tables and a section on the League of Nations. A voluminous index enhances the value of this well-arranged volume.

Lands of the Thunderbolt: Sikhim, Chumbi, and Bhutan. By the Earl of Ronaldshay. Pp. xvii + 267 + 32 plates. (London, Bombay and Sydney: Constable and Co., Ltd., 1923.) 16*s.* net.

THE barest record of the journeys made by Lord Ronaldshay from Darjeeling into Sikhim, Chumbi, and Bhutan, could scarcely fail to be of interest. Sikhim is probably the most mountainous country in the world, while both Chumbi and Bhutan are little known to Europeans. Lord Ronaldshay's record, however, has the added attraction that he is intensely interested in the curious lines of thought of the peoples he met. These are the result of that combination of Buddhism and the animistic beliefs of primitive Tibet which we know as Lamaism. In Lamaism, the rationalistic philosophy of Buddhism, of which the author gives a succinct account, coexists side by side with a belief in "devils," and the efficacy of the praying wheel, a reverence for repetition and an unquestioning faith in number, most strikingly manifested in the endless reiteration of religious formulæ as an effective exercise of piety. The result of the incongruous combination is strikingly manifested in a weird ceremonial in which such observances as the devil dances of the Black Hat and the bizarre pantomimic dances of Bhutan play a prominent part. Lord Ronaldshay's record of his observations is illustrated by a large collection of photographs, many of great beauty, taken by himself.

Food, Health, and Growth: a Discussion of the Nutrition of Children. By Dr. L. Emmett Holt. Pp. xi + 273. (New York: The Macmillan Company; London: Macmillan and Co., Ltd., 1922.) 7*s.* 6*d.* net.

THIS book embodies a series of five lectures on certain important and interesting topics relating to child nutrition. The objects are to demonstrate the relation of nutrition to health and growth, to state the requirements of children during the period of growth, and to discuss how these requirements may best be met. Considerable attention is paid to the accessory food factors.

The most important chapter is the last, which deals with practical measures. Dr. Holt believes that the only way of dealing with health problems, including that of errors of nutrition, is by education of children in matters of personal hygiene, and he suggests that much can be done in schools to make the teaching of health interesting and its practice attractive.

The book contains much that is useful and interesting to the general reader, and its understanding requires no previous scientific knowledge of nutritional principles.

The Chemists' Year Book, 1923. Edited by Dr. F. W. Atack, assisted by L. Whinyates. Vol. I. Pp. iv + 422. Vol. 2. Pp. vii + 423-1107 + xv. (Manchester: Sherratt and Hughes, 1923.) 2 vols., 21*s.* net.

"THE Chemists' Year Book," which is the English equivalent of the "Chemiker Kalender," is now approaching the latter in completeness. In the present issue there has been some revision, and a new section, on "Leather Analysis," has been added. It is worth considering whether the space taken up by such descriptions of analytical methods, which would usually be sought in special manuals, could not be better used in giving further numerical data. Thus, the section on thermochemical data, or sections rather, since the material is dispersed, cannot compare with the information in the "Chemiker Kalender." The price is also very high for a book which is to be replaced every year.

Letters to the Editor.

Effect of Infinitesimal Traces of Chemical Substances on Photosynthesis.

THE possibility of ultra-measurable traces of certain chemical substances affecting assimilation is a matter of much importance in physiology. The carbon-assimilation of water-plants affords an extremely sensitive process for the investigation of the subject. The usual method of counting the number of bubbles of oxygen given out by the plant under light is, however, most untrustworthy for quantitative determinations, since the size and frequency of the bubbles undergo spontaneous variation. This difficulty has been completely removed by a new device which I have been able to perfect, by which the evolution of *equal volumes* of oxygen is automatically recorded on a revolving drum by an electromagnetic writer; records thus obtained enable us to determine the normal rate of photosynthesis and its induced variations. I have also found that there is a definite relation between the evolution of oxygen and the formation of carbohydrate in the leaf. The automatic apparatus referred to can be so adjusted that the successive dots in the record represent the photosynthetic production of amounts of carbohydrate as small as a millionth of a gram. It is impossible in this short communication to give a detailed account of the apparatus, which will be found fully described in my forthcoming work, "The Physiology of Photosynthesis," to be published by Messrs. Longmans.

My attention was directed to the possible effect of traces of chemical substances on carbon-assimilation by the extraordinary increase in the photosynthetic activity after the thunderstorm and rain which lasted from February 10 to February 13 of this year. The coefficient of photosynthetic activity of the aquatic plant, *Hydrilla verticillata*, growing in the pond of the Institute, had been carefully determined for January and for the first week of February, and found to be practically the same in different specimens. The coefficient for light, *i.e.* the ratio of increment of activity to the increment of light, was found to be 13·2 per 100 lux immediately before the thunderstorm (February 9); whereas after the thunderstorm it was found to be 26·9, the activity having been thus increased 100 per cent; later the value decreased by stages to 22·9, as if the beneficial effect of the thunderstorm were subsiding to a certain extent. There was no variation of temperature, which remained constant at 22° C.

The rain could not have produced any variation of turgor in the plant, which was submerged in water. A plausible explanation of the enhanced activity is that the electrical discharges during the thunderstorm produced oxides of nitrogen which, washed down by the rain, added traces of nitric acid to the water of the pond in which the plants were growing. The quantity thus added would, however, be inconceivably minute. The correctness of the above hypothesis may for the present be left an open question. There can, however, be no doubt that minute traces of nitric acid exert a potent influence on photosynthetic activity, as is shown by the results of the following experiments carried out under constant light and temperature. At first I applied a dilution of one part in ten thousand which caused a depression of activity. I therefore went to the other extreme and prepared different dilutions of 1, 10, and 100 parts in 100,000,000,000. It is difficult to form any clear conception of ultra-measurable quantities from a row of zeros, and I will therefore, following the French system of measurement, designate a thousand millions as a billion. Application of a solution of one part of nitric acid in 100 billions induced no change in photosynthesis, but one part in 10 billions produced a marked increase in activity of about 100 per cent; 1 part in 2 billions caused a further increase of nearly 200 per cent. This was the climax. The enhanced activity underwent a slight decline at dilutions of one to ten parts in a billion, the activity being still greater than the normal by 100 per cent. There was an abrupt depression of activity at lower dilutions than 1000 parts in a billion (Fig. 1). The above figures may be taken to be typical of the effect of traces of nitric acid; for a dozen different specimens taken at random gave very similar results. In subtonic specimens, with

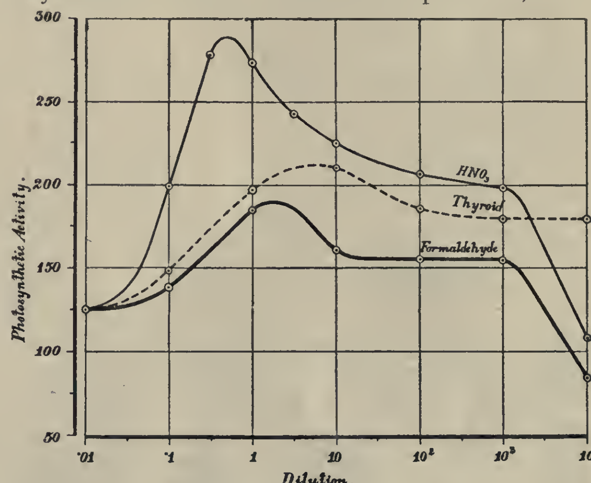

FIG. 1.—Curves showing effects of traces of nitric acid, of extracts of thyroid gland, and of formaldehyde, on the activity of carbon assimilation by the aquatic plant *Hydrilla verticillata*. The ordinals represent induced change in photosynthetic activity, the normal being taken as 100; the abscissæ represent dilution from 0·01 to 10^4 parts in a billion.

photosynthetic activity at standstill, an addition of two parts nitric acid in ten billions caused vigorous photosynthetic evolution of oxygen, the renewed activity persisting for a very considerable length of time.

I obtained similar increase in carbon-assimilation with traces of certain other substances of which I will give only two examples. The dotted curve in the middle of the figure exhibits the effect of extract of thyroid gland. Here the maximum activity was produced at a dilution of ten parts in a billion. The noticeable fact is that there was no reversal for a considerable range: the increased activity of about 80 per cent persisted up to the lower dilution of one part in a million.

The effect of traces of formaldehyde, which is a highly poisonous agent, is of much theoretical interest. A dilution of one part in a billion caused an increase of photosynthetic activity by 85 per cent. At higher concentrations, formaldehyde produced its normal poisonous effect. The action of traces of formaldehyde has special significance in regard to the "first product" of assimilation. According to Baeyer's theory, formaldehyde is one of the first products from which carbohydrates are formed by polymerisation. This theory labours under the difficulty that formaldehyde is extremely poisonous to plants.

The experiments just described, however, show that minute traces of formaldehyde are by no means poisonous, but actually enhance photosynthetic activity in a remarkable degree. The intermediate stages of transformation from formaldehyde to carbohydrate are likely to be rapid; there would therefore be no accumulation of formaldehyde to a poisonous degree.

At first sight it is inconceivable that infinitesimal traces of certain chemical substances could have such a potent influence on life-activity. There is, however, no doubt of the reality of the phenomenon.

J. C. BOSE.

Bose Institute, Calcutta.

Molecular and Crystal Symmetry.

I GATHER from Messrs. Shearer and Astbury's reply (NATURE, June 2, p. 740) to my former letter to NATURE (May 12, p. 632) that my mention of a paper by Fedorov has unhappily diverted their attention from the main issue. As any attempt to disentangle numerous side issues would only take up valuable space, I propose to confine my remarks to the few points connected with recent X-ray developments.

In attempting to show that I was in error in supposing that nothing can be said about the symmetry of the molecule until the position of every atom in it is determined, Shearer and Astbury invoke the X-ray evidence of benzoic acid; but it will be found on examination that their proof rests on an assumption that if two crystal molecules are symmetrically disposed with regard to a structural plane the molecular symmetry is thereby limited. My own view is that the molecular symmetry remains untouched, and that the actual X-ray results can be equally harmonised with any type of molecular symmetry, provided the molecules be orientated in a general way, *i.e.* so that no molecular plane or axis of symmetry be parallel to any structural plane or axis. What is, indeed, wanted is an experimental proof that a structural plane beset with molecules, individually symmetrical but facing the plane asymmetrically, is distinguishable from a plane studded with asymmetric molecules; but as such an experiment is unrealisable, I do not see how the symmetry of an individual molecule can be deduced without first determining the positions of every atom in the structure. Further, I fail to see how Messrs. Shearer and Astbury can take a different view, for if the molecular symmetry of a complex organic compound can be deduced from X-ray measurements, what object was there in advancing Shearer's rule? If it were really feasible, it would surely be better to solve the intimate structural details of benzoic acid by the method of experiment than by a process of speculation.

The only other subject I need refer to is that of tartaric acid. It now appears that my previous conjecture, that Astbury's crystal molecule is axially symmetrical, was erroneous, and that this substance is really in formal agreement with Shearer's rule. I may, however, point out that I was formerly particularly adverse to drawing any definite conclusion from such a complicated structure, a position which I see no reason to modify. In this connexion it is pertinent to add that evidence from simple compounds is already coming in. Dickinson's recent investigation of tin tetraiodide reveals 8 chemical molecules, each of a symmetry number 6, to the unit of structure; and as the symmetry number is generally held to be 24 (and not 48) the rule is correspondingly infringed.

In conclusion, it may be useful to add a word of explanation on the part played by Shearer's rule in X-ray investigations of organic compounds. In the typical case of benzoic acid classical methods of crystallography allow of the determination of the symmetry and also of the relative edge-lengths of the unit of structure. Building on this foundation the X-ray method goes further by determining the mass associated with this unit, its absolute dimensions and therefore volume, and, somewhat approximately, the relative positions of the centres of gravity of its constituent molecules. This represents a great advance to the crystallographer, but scarcely so to the chemist unless such molecular centres can be expanded into bodies of definite shape and atomic configuration. Now as volume determines neither external shape nor internal structure the problem is obviously one of great complexity, and X-ray results cannot usefully be applied to its solution on account of the enormous number of variables concerned in crystals of low symmetry and complex chemical composition; consequently, more general but less direct aids have to be relied on.

One method of bridging the gap is to adopt the hypothesis that atomic radii are approximately constant in crystals, whereby a radius determined from an element or simple inorganic compound can be carried over to a complicated organic compound. By such means spheres of appropriate sizes can be packed together in a tentative way so as to fill variously shaped cells of the correct volume, but there is obviously still much scope for varieties of arrangement and some further limiting principle is needed. That actually favoured at the present moment is Shearer's rule that a crystal makes the utmost use of the symmetry of its component molecules, or, alternatively stated, that the molecular symmetry is deducible as being the crystal symmetry divided by the number of molecules involved in the unit of structure. Since such a rule generally leads to low molecular symmetries (*i.e.* those which are practically consistent with any given arrangement), it is somewhat difficult to see how it can serve to limit the number of structural solutions. It can, however, be employed in a more superficial way, since the creation of an upper limit to molecular symmetry serves to rule out any stereochemical formulæ of still higher symmetry. Thus, it has been suggested that the Kekulé and Claus formulæ for benzene must be abandoned in favour of the Dewar formula, at any rate in the crystal.

Such results are obviously worthy of attention in so far as Shearer's rule is true. The present position is that the rule is a postulate and so also are the results that flow from it, ranging from the disposition of electrons in a crystal molecule of alumina to that of the atoms in any complex organic compound.

T. V. BARKER.

Stirling's Theorem.

MR. H. E. SOPER, in NATURE of May 5, p. 601, gives Stirling's Theorem in the form

$$n! = \sqrt{2\pi}\left(\frac{n+\frac{1}{2}}{e}\right)^{n+\frac{1}{2}} \times \exp.\left\{-\frac{1}{24(n+\frac{1}{2})}+\frac{7}{2880(n+\frac{1}{2})^3}+\ \cdot\ \cdot\ \cdot\ \right\}.$$

This form suggests that a first approximation of the form $\sqrt{2\pi}\left(\dfrac{n+\frac{1}{a}}{e}\right)^{\left\{n+\frac{1}{a}\right\}}$ might be made exceedingly accurate by choosing a in a suitable way.

Commencing in a similar way to that of Mr. Soper, we have

$$\log\left(n+\frac{1}{\alpha}\right)! - \log\left(n+\frac{1}{\alpha}-1\right)! = \log\left(n+\frac{1}{\alpha}\right),$$

where $n!$ is generally $\Gamma(n+1)$.

Now

$$\log\left(n+\frac{1}{\alpha}\right)! - \log\left(n+\frac{1}{\alpha}-1\right)! = e^{D/\alpha}(1-e^{-D})\log n!,$$

$$\therefore \log n! = \frac{e^{-D/\alpha}}{1-e^{-D}}\log\left(n+\frac{1}{\alpha}\right),$$

where D is the differential operator.

$$(1-e^{-D})^{-1} = \frac{1}{D}\left\{1+\frac{D}{2}+\frac{D^2}{12}-\frac{D^4}{720}\ \dots\right\},$$

$$e^{-D/\alpha}(1-e^{-D})^{-1} = \frac{1}{D}\left\{1+D\left(\frac{1}{2}-\frac{1}{\alpha}\right)+D^2\left(\frac{1}{12}+\frac{1}{2\alpha^2}-\frac{1}{2\alpha}\right)\right.$$

$$+D^3\left(-\frac{1}{3!}\frac{1}{\alpha^3}+\frac{1}{4}\cdot\frac{1}{\alpha^2}-\frac{1}{12\alpha}\right)$$

$$\left.+D^4\left(-\frac{1}{720}+\frac{1}{24\alpha^2}-\frac{1}{12\alpha^3}+\frac{1}{4!\,\alpha^4}\right)\dots\right\},$$

$$\frac{1}{D}\log\left(n+\frac{1}{\alpha}\right) = \left(n+\frac{1}{\alpha}\right)\left\{\log\left(n+\frac{1}{\alpha}\right)-1\right\},$$

$$D\log\left(n+\frac{1}{\alpha}\right) = \frac{1}{n+(1/\alpha)}.$$

. . . .

$$\therefore \log n! = \left(n+\frac{1}{\alpha}\right)\left\{\log\left(n+\frac{1}{\alpha}\right)-1\right\}+\left(\frac{1}{2}-\frac{1}{\alpha}\right)\log\left(n+\frac{1}{\alpha}\right)$$

$$+\frac{1}{2}\left(\frac{1}{6}+\frac{1-\alpha}{\alpha^2}\right)\frac{1}{\left\{n+\frac{1}{\alpha}\right\}}$$

$$+\left(\frac{1}{3!\,\alpha^3}-\frac{1}{4\alpha^2}+\frac{1}{12\alpha}\right)\frac{1}{\left\{n+\frac{1}{\alpha}\right\}^2}$$

$$+\left(-\frac{1}{360}+\frac{1}{12\alpha^2}-\frac{1}{6\alpha^3}+\frac{1}{12\alpha^4}\right)\frac{1}{\left\{n+\frac{1}{\alpha}\right\}^3}$$

+a constant,

i.e.

$$n! = \sqrt{2\pi}\left(\frac{n+(1/\alpha)}{e}\right)^{n+(1/\alpha)}\times\left(n+\frac{1}{\alpha}\right)^{(\alpha-2)/2\alpha}$$

$$\times\exp.\left[\frac{1/6+(1-\alpha)/\alpha^2}{2\{n+(1/\alpha)\}}+\dots\right]. \quad (1)$$

It will easily be seen that this reduces to Mr. Soper's form if α is taken to be equal to 2.

As a first approximation to the value of $n!$ we have

$$n! = \sqrt{2\pi}\left(\frac{n+(1/\alpha)}{e}\right)^{n+\frac{1}{\alpha}}\left(n+\frac{1}{\alpha}\right)^{(\alpha-2)/2\alpha}.$$

To make this the best possible first approximation, it is necessary to choose α so that the first term of the exponential series is zero, *i.e.*

$$\frac{1}{6}+\frac{1-\alpha}{\alpha^2}=0$$

is an equation for determining α, *i.e.*

$$\alpha^2-6\alpha+6=0.$$

The roots are $3\pm\sqrt{3}$ or 4·73205081 and 1·26794919. Approximately these roots are 19/4 and 5/4.

To decide which of these two values would be the better, the values of the coefficients of the next two terms of the exponential were determined for each value of α, and it was found that these values were practically of the same order of magnitude. I have chosen to take the lower value, because $\{n+(1/\alpha)\}$ will be greater for that value.

[At first it occurred to me that the desired result would be obtained by making the first term involving α in the exponential a minimum; but although a minimum it might be negatively large, so this criterion had to be ruled out. However, it was noticed that $\alpha=2$, which Mr. Soper uses, is practically the value of α which makes this term a minimum, especially for the larger values of n.

The condition for a minimum is that α should satisfy the equation

$$\alpha^2(6n+1)-12\alpha n-6=0,$$

i.e. α would be a function of n.

It is the positive root which concerns us, and it will be seen that as n increases this root tends to the value 2,

$$\alpha = 2+\frac{1-\frac{1}{4n}}{(6n+1)}, \text{ approx.}$$

Thus for the range of α values which makes the first term of the exponential negative, $\alpha=2$ is the worst possible choice in finding a good first approximation.]

Taking $\alpha=3-\sqrt{3}$, our series for $n!$ becomes

$$n! = \sqrt{2\pi}\left(\frac{n+b}{e}\right)^{n+b}(n+b)^{-c}$$

$$\times\left\{1-\frac{0{\cdot}0080{,}1875}{(n+b)^2}-\frac{0{\cdot}0004{,}6296}{(n+b)^3}\ \dots\right\}, \quad (2)$$

where $b=0{\cdot}7886{,}7513$, $b-c=\frac{1}{2}$, $c=0{\cdot}2886{,}7513$.

The value $\alpha=5/4$ was used in some calculations, and although the series then looks simpler, there is really nothing to be gained by taking this value; this is especially so for the computer who has a calculating machine. It will be noticed that our first approximation in (2) will be affected by an error of the order of $1/125n^2$ of its own value.

First approximation:

$$n! = \sqrt{2\pi}\left(\frac{n+b}{e}\right)^{n+b}(n+b)^{-c}. \quad . \quad . \quad (3)$$

This approximation was tested on a comparatively small value of n, $n=10$, $\log 10! = 6{\cdot}5597931$, *i.e.* $10! = 362{,}9051$.

Mr. Soper's first approximation $\sqrt{2\pi}\{(n+\frac{1}{2})/e\}^{n+\frac{1}{2}}$ gives $\log 10! = 6{\cdot}5614855$, *i.e.* $10! = 364{,}3221$.

The correct value is 362,8800; the error in the first case is only 251, while the error in the second is 14,421.

Extending the idea, we come to consider the Second Approximation. In the British Association Report for 1883, p. 407, Prof. A. R. Forsyth deduces a very pretty result for $n!$:

$$n! = \sqrt{2\pi}\left\{\frac{\sqrt{n^2+n+1/6}}{e}\right\}^{n+\frac{1}{2}}. \quad . \quad . \quad (4)$$

This compact result is obtained by a process which is essentially the same as the above, but applied to the second term of the exponential instead of the first. If we attempt to find α so that this term may be zero, it is necessary to solve a quartic in $1/\alpha(=x)$.

$$36x^4-24x^3-24x^2+12x+1=0.$$

[The term we are considering is

$$\left[\frac{1}{2}\left(\frac{1}{3\alpha^3}-\frac{1}{2\alpha^2}+\frac{1}{6\alpha}\right)+\frac{1}{2!}\left\{\frac{1}{2}\left(\frac{1}{6}+\frac{1-\alpha}{\alpha^2}\right)\right\}\right]\frac{1}{\left\{n+\frac{1}{\alpha}\right\}^2}.]$$

There are two positive roots, both between 0 and 1. The greater is the more suitable for our series. It is very nearly equal to unity and it was found to be very nearly 32/33.

As a second approximation $n!$ is then equal to

$$\sqrt{2\pi}\left(\frac{n+(1/a)}{e}\right)^{n+(1/a)}\left(n+\frac{1}{a}\right)^{(a-2)/2a}\left[1+\frac{1/6+(1-a)/a^2}{2\{n+(1/a)\}}\right], \quad (5)$$

where $1/a=32/33$.

From this expression, which is affected by an error of order $-1/360n^3$, $10!$ was calculated:

$10!=362,8806$ (an error of 6).

The approximation (4) gives

$10!=362,8787$ (an error of 13).

From the original value of a, the second approximation will be

$$n!=\sqrt{2\pi}\left(\frac{n+b}{e}\right)^{n+b}(n+b)^{-c}\left\{1-\frac{\cdot 0080,1875}{(n+b)^2}\right\}. \quad (6)$$

The error in this case will be less than $1/2000\times n^3$ of the whole.

(6) gives

$10!=362,8801$ (an error of 1).

Forsyth's approximation (4) has an error of order $1/240n^3$. It will be seen that the first approximation (3) is a remarkably good one, and the expression is quite good for calculation purposes. The value of $n!$ may be calculated in a very short time.

Mr. Soper's expansion, taken to the same order as (4), gives

$10!=362,8792$ (an error of 8),

with an error of order $1/400n^3$. The second approximation (6) derived in the same way as our first approximation is exceedingly accurate, and is better than that of (4); it is also better than Mr. Soper's, which in turn is better than Prof. Forsyth's (4).

Prof. K. Pearson has given in *Biometrika*, vol. vi., a very close approximation to the value of $n!$ This takes account of terms up to $1/n^4$ and partially of the term in $1/n^5$:

$$\log\frac{\Gamma(n+1)}{n^n e^{-n}}=0\cdot 3990899+\tfrac{1}{2}\log n + \cdot 080,929\sin\frac{25^\circ\cdot 623}{n}. \quad (7)$$

On evaluating $10!$ by means of this expression, it is found that the exact value is given to the nearest unit.

My chief aim in this note has been to show that a very good first approximation may be obtained without the use of any terms of the exponential and that the resulting expression is useful for computing factorials.

It may be of interest to give the values of 1! 2! and 10! found from these approximations in a single table:

	(3) of Present Note.	(4) Forsyth.	(7) Pearson.	Exact.
1!	1·00248	·99883	·99952	1·00000
2!	2·00266	1·99948	1·99996	2·00000
10!	362,9051	362,8784	362,8800	362,8800

JAMES HENDERSON.

Biometric Laboratory,
University College, London.

Dr. Kammerer's Alytes.

MAY I reply in a few words to Dr. Bateson's brief letter on Kammerer's Alytes, which appeared in NATURE of June 30?

Dr. Bateson states that when the nuptial callosities of genera allied to Alytes are described as appearing on the "inner" sides of the fingers, the word "inner" means the radial side and not the palmar surface.

This is quite true, but the callosity on the radial edge of the finger involves the palmar surface also, as Dr. Bateson may convince himself by inspecting Boulenger's figures, and as, indeed, is demonstrated to every student when he is shown the nuptial callosity of the male Rana.

Further, I learn from a letter from Dr. Kammerer that in the specimen of Alytes shown at the Linnean Society, the callosities extend round the radial edges of the fingers on to the dorsal surface, and that he would have demonstrated this to any one who had raised this point while he was explaining his specimens before the meeting.

Readers of NATURE are thus now in a position to judge what ground there was for Dr. Bateson's objections.

Molecular Interruption.

IN reply to Mr. R. d'E. Atkinson's criticism (NATURE, March 10, p. 326) of my note on the possibility of selective molecular interruption, I should like to point out that so far from attempting to dispose of the validity of the ordinary treatment and claim the effect in question for "infinite free path," I had already shown (NATURE, July 22, vol. 110, p. 112) the reverse to be the case, and that such an effect is not then possible.

It is manifestly clear that it is illogical to conclude, however, because this is the case with "infinite free path" (*i.e.* in the absence of intermolecular collision in the system), that it must also be true for a system in which intermolecular collisions exist, with long free paths relative to the diameter of the directing vessel employed, the particular and special case alone dealt with in my note.

Mr. Atkinson's misinterpretation appears to have arisen from his overlooking my words "molecules issuing from collision in circle O," since his statement "all points on their long paths may equally be taken" as being in O is otherwise unintelligible.

His statement that I have admitted the length of the free path to be irrelevant is not correct. The excessive downward bias to which he refers is, in my opinion, due entirely to the fact that molecules proceeding from collisions (with equal probability of motion in all directions) are interrupted by the vessel before the end of their normal free path period, *when they are moving in certain specific directions*; and are uninterrupted throughout the whole of their normal flight, *when they are moving in other specific directions*: a selective redirection or elimination of the former class which must continuously be leaving a corresponding preponderance of the latter—a conclusion which more careful calculation confirms.

ARTHUR FAIRBOURNE.

The Transport of Rocks.

MAY I ask Prof. Grenville A. J. Cole, through the medium of your columns, how far the authority for the statement that "the Portuguese stone . . . was brought in carracks round the Cape to build the jutting fort on the coral shore of Moçambique" (NATURE, March 17, p. 353) is to be regarded as trustworthy?

I first saw this fort in 1911, and as recently as September last year I walked all round it. I have never been inside, but I am told by Portuguese residents on the island that the same kind of stone has been used throughout in the construction of the fort. This stone is a sandy coral-rock, with occasional small pebble bands. The country rock of Moçambique island is also a coral rock identical in composition and fossil contents—so far as one can judge by hand specimens and very numerous exposures—with that of which the fort is built. This material occurs in vast quantities on the eastern coast of Africa, and indeed on many tropical coast belts: it is well seen at Mombasa and Zanzibar, which island, like that of Moçambique, consists of little else. The coral-rock is not the best material for constructional purposes, as an examination of the external walls of the fort is sufficient to show. Can it be that this material was shipped all round the Cape? It may be so, but I find it difficult to believe.

E. J. WAYLAND.

Fort Portal, Uganda, May 3.

IN reply to the interesting letter from Mr. Wayland of the Geological Department of Uganda, I beg to say that my authority for the statement that the fort of Moçambique was built of stone brought from Portugal is the uninitialled article in the "Encyclopædia Britannica," 11th ed., vol. 18, p. 949, where we read: "There are three forts, of which the principal, St. Sebastian, at the northern extremity of the island, was built in 1510 entirely of stone brought from Portugal."

I have examined the coral-rock here and at Mombasa, and, as Mr. Wayland states, it is not attractive for building purposes. I cannot speak as to the outer wall of the fort, and it may have been rebuilt or refaced since 1510. It would be interesting now to pursue the matter in some detailed history of Moçambique.

GRENVILLE A. J. COLE.

On Auroral Observations.

IT has been found that the green auroral line is regularly visible in the clear night sky, and Lord Rayleigh has discovered the remarkable fact that it is more intense at Terling than in the north of England. A cognate investigation, which, so far as I know, has not yet been made, may be suggested to auroral observers, namely, to examine how the intensity changes at any one place throughout the night. The observation is doubtless a difficult one, but might be made by exposing a series of plates at different hours on a succession of clear nights. It would be of great interest to know whether or not the intensity remains nearly uniform throughout the night hours.

Gradient of Potential near Electrodes.

IN NATURE of March 31, p. 431, Messrs. H. Nagaoka and Y. Sugiura describe a method of observing the Stark effect in the iron arc; namely, in the thin layer at the surface of the lower electrode. This fact points to the existence of a considerable gradient of potential in this layer.

In the course of an investigation of the radiation in the spark I have found, by means of direct electric measurements, the existence of a considerable gradient of potential in the thin layer that surrounds the electrodes when the sparking discharge takes place.

The discharge of 952 sparks per sec., yielding an effective current of 24 milliamperes, shows that the change of the difference of potential depends upon the length of sparks, as the accompanying diagram (Fig. 1) shows. If the sparks are so short that the thin layers in the proximity of the electrodes, which yield a metallic spectrum, are not yet divided, then there exists a great gradient of potential (Fig. 1, I). The size of gradient depends first upon the nature of the metal forming the electrodes. This is shown by the two curves on the diagram for electrodes of platinum and aluminium.

At longer sparks, while among the above-mentioned layers only a spectrum of gas appears, the gradient of potential is much less (Fig. 1, II); this does not depend upon the nature of the electrodes.

The intermediate space, marked by interrupted lines, is difficult to examine. Sparks of both kinds generally come into view.

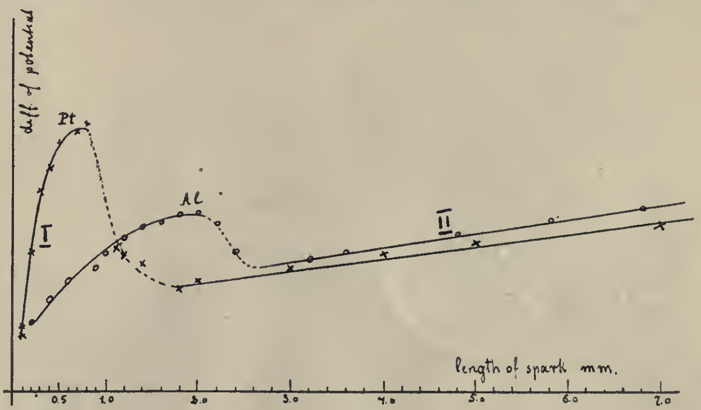

FIG. 1.

If V_1 signifies the difference of potential for short sparks, and V_2 that for long sparks, we get for platinum and aluminium electrodes about:

$$\left(\frac{\text{grad. } V_1}{\text{grad. } V_2}\right)_{Pt} = 10 \qquad \left(\frac{\text{grad. } V_1}{\text{grad. } V_2}\right)_{Al} = 5$$

The thickness x of the layer where there is a considerable gradient of potential is small:

Pt.	Cu.	Al.
$x = 0.4$	0.4-0.5	0.7-0.9 mm.

This investigation is being continued.

The Tides.

THE notice in NATURE of April 14, p. 508, of my pamphlet on the tides implies that I have completely misunderstood "the theory of the tide-generating force on the principle of gravitation." Regarding this I would like to present to your readers, very briefly, just one point in that theory: Newton, Herschel, and many other authorities compute the principal tide-raising force as the difference between the moon's attraction at the earth's centre and at the earth's surface. Now this is exactly the method

that would be employed if the sea were about 4000 miles deep. But the sea is only about 2 miles deep, in which, obviously, the tide would be practically insensible compared with that in a sea 4000 miles deep. The height of the tide is measured from the sea bottom; so that whatever elevation by tidal action of that bottom, which takes place, is not added to the height of the tide at all. Why, then, should the action of the tide-raising force beneath the bottom of the sea be added to that action within the sea itself (as is invariably done) to obtain, or explain, the ocean tide?

There are many other points of the tidal theory discussed in the pamphlet referred to which are equally difficult of explanation according to the theory of gravitation. To a statement of these difficulties it is really a rather unsatisfactory answer to say merely that their presentation betrays "a complete misunderstanding of the theory." Facts should be given to show of just what the misunderstanding consists; and truly such facts would not be a waste even of the columns of Nature, but would undoubtedly prove edifying to many of your readers besides the present writer.

The "Tides" pamphlet will be sent free on request to any one interested. Evan M'Lennan.

Corvallis, Oregon, U.S.A.,
May 26.

To any one who understands the theory of gravitation, Mr. M'Lennan's letter is a complete justification of the note. To those who would think that there might possibly be something in it, nothing less than chapter v. of Sir G. H. Darwin's popular book on tides would be of any use. There are too many important and pressing demands upon the space of Nature to permit a full discussion of the points put forward by Mr. M'Lennan. We can only remark that the tides are due to the difference between the response of the oceans and the solid earth to the attractions of the sun and moon. The motion of the solid earth as a whole is determined by the forces at its centre, so that the differential motion of the oceans is determined by the vectorial excess of the forces at the earth's surface over those at its centre. Of this excess it is the component *tangential* to the earth's surface which is effective in producing the tides. The Writer of the Note.

Barometric Pressure in High Latitudes.

In his letter (Nature, May 12, p. 634) on the subject of the causation of anticyclones, recently under discussion, Mr. R. M. Deeley makes two statements which cannot, on the most liberal interpretation of their face value, be reconciled with the real facts of the case as they are well known to meteorologists.

First of all he says: "Another clear effect of surface temperature is the fact that the North Pacific cyclone and the North Atlantic cyclone (the eyes of the North Polar cyclone) are more powerful during the summer than they are during the winter." This is in direct opposition to the truth, as any one will find who refers to charts of mean pressure for January and July, wherein he will find the Icelandic and Bering Sea minima greatly accentuated in winter and nearly obliterated in summer. Moreover, these mean or average charts are merely the generalised expression of one of the most obtrusive facts of seasonal climatology; namely, the frequently violent cyclonic mood of the North Atlantic ocean in mid-winter, and its generally much milder state at mid-summer, together with the many more gales we experience in England in December and January than in June and July.

Secondly, Mr. Deeley refers to "the striking facts that throughout the year the great low-pressure areas are over the frigid poles." Now though there may be relatively low pressure with cyclonic circulation at higher atmospheric levels round the poles, the modern work of Dr. G. C. Simpson for the Antarctic, and of Prof. Mohn for the Arctic, indicate that the *surface* pressure at both poles is relatively high, supplying an outflow of air towards the low pressure belts about latitudes 60° N. and S. In the Antarctic there is a true glacial anticyclone; in the Arctic the land areas round the polar basin complicate the distribution of pressure, but the pressure over that basin is relatively high throughout the year, particularly in winter, when it links the interior glacial anticyclone of Greenland with the continental anticyclone of Siberia.

Moreover, if the Polar Front theory of Prof. Bjerknes is true—and though there are justifiable doubts as to whether that theory is a full dynamical explanation of cyclonic circulation, no weather forecaster will dispute that it provides an excellent geographical background of reference for the facts associated with that circulation—there *must*, on the average, be relatively high surface pressure about the poles.

With regard to the effect of surface temperature on pressure it is quite true (as Mr. Deeley observes) that in the northern hemisphere, where there are such violent contrasts of continent and ocean, the continents command the excess of air in winter on account of the cold, but lose it to the oceans in summer on account of the heat. But this relationship between surface temperature and pressure is only very rough. There cannot be high or low pressure *everywhere*; and the actual result is a highly complicated regional compromise. If the northern hemisphere were all land or all water, there could not be those marked seasonal or monsoonal disturbances, so conspicuous on the January and July charts of mean pressure, of the simple dynamic belts of wind and pressure, namely, low at the equator, high at about 30° N. and S., low again at about 60° N. and S., high again at the poles, to which one gets an approximation on the annual chart and also on those for April and October. One must grant that the circulation of the atmosphere is initiated and maintained by the general thermal gradient between the equator and the poles; but the rotation of the earth and the seasonal contrasts of temperature between continents and oceans combine to impose an exceedingly complex structure upon the circulation. Ionisation Potentials of Copper and Silver.

In their book on "The Origin of Spectra" Foote and Mohler assign ionisation potentials of 7·692 and 7·542 to copper and silver. These are calculated from spectroscopic data. I have recently succeeded in obtaining low voltage arcs in the vapours of these two metals. For copper, a voltage of 7·8 was found, agreeing with the value given above as closely as one would expect from observations on a low voltage arc. For silver vapour, however, the value found and verified by many observations was 6·0 volts. There were indications of a resonance potential at about 3·1 volts.

This work is being continued especially into the spectroscopic region. A. G. Shenstone.

University of Toronto.

The Problem of Cancer.

ONCE again the public is being made to focus its attention on cancer through the activities of the recently constituted British Empire Cancer Campaign. The object of this so-called campaign is to collect large sums of money which will be devoted to the further study of this disease, which annually sweeps away about 40,000 people in England and Wales alone. The new campaign is taking place under the direction of a committee which has been described as influential, but we search in vain for evidence that the committee, as a whole, possesses the necessary qualifications to direct or to suggest research on what is admittedly one of the most difficult problems in biology. There can be no harm in raising money for medical research—it is, in fact, a highly praiseworthy object—but in the interests of those who have provided the money, it is essential that it should be used in the best way, and it does not appear that the new committee, composed largely of medical men practising among the political, wealthy, or aristocratic sections of the community, is a suitable one to direct cancer research.

The *raison d'être* of the new committee is indeed obscure, for there already exists an Imperial scheme—the Imperial Cancer Research Fund—which has been hard at work with the problem of cancer for twenty years. This committee is under the presidency of the Duke of Bedford, who, as a Fellow of the Royal Society and a man of science, has associated himself very closely and practically with the problem for many years. In addition to a large general committee of Imperial flavour, there is also an executive committee specially composed of men in the highest ranks of the profession, practical and scientific. The work of the Imperial Cancer Research Fund is universally admitted to be of a very high order, and, although it has not been possible to elucidate the cause or causes of malignant growths, a flood of light has been thrown and many foolish views have been exposed and confuted by the researches first of Bashford and later of Murray, who have been the scientific directors of the Imperial Cancer Research Fund. Their work has placed the Fund in the forefront of institutes devoted to the special study of cancer.

It is difficult to understand why a second cancer fund —also Imperial—should be started to do the same work as that which has already been admirably done by the first and older Imperial Cancer Research Fund. From several sides comment has been made on this apparent anachronism, and it has been suggested that, while the new campaign might collect money, its distribution should not be left in the hands of the new committee but should be dealt with by scientific bodies like the Royal Society or the Medical Research Council, acting alone or in co-operation with the Imperial Cancer Research Fund; for, after all, the problem is one of the most difficult now being studied in science.

The Position of Cancer Research.

The subject has passed beyond the realms of clinical observation, and clinicians do not possess the requisite education either to add to or even to supervise work which demands highly-trained biologists. It is, indeed, becoming more and more apparent that cancer is not merely a human problem but one of general biology.

There was a time when the word "tumour" was used to include almost every kind of abnormal swelling that was more or less circumscribed. A great many such swellings have now been separated off, as they have proved to be of inflammatory nature. Even among true tumours a distinction has been made into those that are benign and those that are malignant. Formerly tumours were classified according to their shape or consistence, and many terms employed in this period still prevail, although with an altered significance. Examples of this kind may be cited in such names as "fungus," "polypus," "encephaloid," and "sarcoma." Even the word "cancer" is derived from the supposed resemblance of the cut surface of the tumour to the spreading limbs of a crab.

Up to the first third of last century it was commonly held that cancers and suchlike tumours were something foreign to the body; but with the discovery of the cell, Theodore Schwann showed that there was nothing in any tumour that was really heterologous. His researches, continued by Lebert, were immensely extended by Virchow in his great work "Die krankhaften Geschwulste" (1863–67), to which but little has been added or subtracted from a purely pathological viewpoint. He showed that every tumour is the result of a tissue-forming function derived from the constituents of the body, and the real problem of tumour formation to-day is to find what starts this and causes the tissues to behave in an abnormal way. Every tumour represents a breach in the continuity of some tissue, so that, although arising in a tissue and due to the proliferation of that tissue, the new growth, tumour, or blastoma, as it is called, is really inimical to the well-being of the tissue. Its growth is progressive and unlimited. The cells of which every tumour is composed are bolshevistic, anarchical, or autonomous in varying degree. The laws that govern the behaviour of the cells of a tissue towards each other or other cells are violated. The tumour cells are in some mysterious way set free from restraining influences, and, having attained their liberty, behave in a riotous rather than an orderly manner. Although it is common to speak of cancer as something special, there is the same process at work in all tumours, but the degree of autonomy varies in each. If left to themselves, even the most innocent tumours grow progressively, and may become harmful in virtue of their magnitude. Some of the largest tumours known are benign in a clinical sense, while some of the smallest in point of size may be of deadly malignancy.

Basing the classification of tumours on their origin—histogenesis—Virchow separated them into three great classes according to their components. In his first group—simple histioid tumours—there was only one tissue, whereas in the second or organoid tumours two tissues were involved, one being connective tissue, the other epithelial. In his third group—teratoid tumours —the new growth was composed of several tissues arranged in organ-like fashion. Whatever starts the

cells off, the later growth of a tumour is due to the division of its cells. As this growth proceeds, one of two things happens. Either the tissues become pressed upon and flattened out so that the tumour is said to grow "expansively," or the tumour cells invade the other tissues, gradually destroying them, and finally insinuating or infiltrating themselves into lymph-vessels or blood-vessels. Thus they may be swept away and transported to the most remote ends of the circulation, where, being arrested, they again start to grow and produce a secondary or daughter tumour which is a copy more or less perfect of the primary growth.

It is this last peculiarity which compels us to place true tumours or blastomata in a class outside the swellings caused by inflammatory processes, even although the latter present a certain superficial resemblance to blastomata. The tumour cell itself is or carries the actual exciting agent to continued cell growth, and it is when we come to the question of the cause of this extraordinary cell growth that we are in Cimmerian darkness. We do not know whether there is one or many causes of new growths, and our methods of treatment, especially of the more autonomous or malignant growths, are hopelessly defective.

Theories of the Origin of Malignant Growths.

Naturally, various causes of malignant growths have been suggested, and three at least have been seriously studied; namely, irritation, the action of a parasite, and embryonic aberration.

(1) It is widely held that some irritation, physical or chemical, applied over a long period may incite the cells to unusual growth, which ultimately takes an abnormal blastomatous course. In the last few years, many experiments have concurred to show that tar products may be active incitors to tumours both in men and animals. Cancers in man are not infrequently to be seen in association with some chemical or infective irritation.

(2) A second current of thought has centred round the possibility that tumours, and especially cancers, are due to an exogenic parasite of some kind. From the structure of primary and secondary growths it is necessary to assume that if there is a parasite it must not only incite the cell to division, but also actually be intracellular, for the cells of a secondary distant tumour are the descendants of those that compose the primary tumour. For example, a cancer may arise from the liver. It is composed of liver cells; it may actually, although in an imperfect way, secrete bile. Such a tumour may be carried to the brain, and there we again find that the tumour is composed, not of brain but of liver cells, and it may actually produce bile. If such a tumour is due to a parasite the latter must be inside the tumour cells. Many attempts have been made to find parasites. It must be admitted, however, that up to the present no one has found a parasite in the cells of a tumour which produces a similar tumour in the homologous or heterologous species.

(3) The failure to find a parasite led to another theory—that tumours arise from some embryonic aberration. This view is associated with the names of Durante and Cohnheim, and in certain cases is undoubtedly to be accepted as the probable cause, if it is agreed that there is a high degree of specificity among cells. There is much reason to believe that cells retain their specific characters, or, as Bard has expressed it, "Omnis cellula e cellula ejusdem generis." If this is correct, as it appears to be, one can explain the occurrence of heterotopic tumours best upon an embryological basis. Thus the occurrence of a tress of hair, a tooth, a piece of cartilage, and fragments of lung or intestine in a dermoid tumour of the ovary of a virgin is explicable best on some embryological aberration. It is impossible to believe that the occurrence of 1000 teeth in a tumour of the jaw can be produced by a parasite.

While, however, Cohnheim's theory may explain some growths, there are others which do not come into this category. The degeneration of the process of growth, which is one of the main features of tumours, is evidently some very fundamental process, for growths benign and malignant are found in all animals from fish upwards. Although this fact does not explain the cause of cancer, it dispels many of the foolish theories which have been brought forward to explain cancer in man.

Up to the present time, the histological structure of tumours has been very extensively studied all over the world, but it is increasingly apparent that this method alone has great limitations. In consequence, it has given way to the study of malignant tumours which can be successfully transplanted from one animal to another of the same species. Many facts connected with the origin and spread of, and immunity to growths have been established by this kind of investigation.

In more recent times the physiological processes in cancer tissue have been investigated, as well as the production of malignant tumours in animals, by the application of chemical substances like tar or the chemical substances produced by the concurrent development in the animal of certain animal parasites, as was shown by the extended researches of Johannes Fibiger in Copenhagen.

Another line of work has concerned itself with the growth of tissues *in vitro*. It is probable that much light will be thrown upon the whole of the blastomatous processes by work of this kind. The field of cancer research in man is limited on account of the fact that he is outside the pale of experimental analysis. Methods of treatment may be tried to cure such a desperate disease, but it is reasonable to demand that there should first be some experimental basis for the treatment.

The main point, however, is that all over the world the highest class of scientific workers are busily engaged in trying to solve one of Nature's great mysteries which affects both man and almost all known animals. Cancer is a dreadful, inscrutable disease, and, however blunted medical men become from constant association with other diseases, they never become immune to the sufferings of the cancer patient. Although the main cause of the trouble is unsolved, it is not to be imagined that the research world is standing still. On the contrary, there is everywhere a pulsation which indicates that we are getting nearer the solution of the mystery.

W. B.

The Rotation of the Earth and its Influence on Optical Phenomena.[1]

By Prof. H. A. LORENTZ, For. Mem. R.S.

THERE are different ways in which, by means of optical phenomena, the motion of a system can be detected. I shall speak of them successively, with a view especially to the rotation of the earth, briefly considering also the optical effects that are due to the annual motion, which can be taken to be a translation.

1. DOPPLER'S PRINCIPLE.—In the first place there is Doppler's principle. If r is the distance from a luminous source to an observer (or to the slit of the spectroscope), $v_r = dr/dt$ the relative velocity in the direction of the line r, and n the real frequency of the light emitted by the source, the observed frequency will be $n+\delta n$, where

$$\delta n = -\frac{v_r}{c} n,$$

c being the velocity of light. The corresponding change of the wave-length λ is given by

$$\delta\lambda = \frac{v_r}{c}\lambda.$$

The velocity of the earth's translational motion is 30 km./sec., *i.e.* $\frac{1}{10000}c$. It can give rise for yellow light to a change in wave-length of about half an Ångström unit. The displacement of spectral lines produced by it is perfectly observable; in fact, star velocities of some 50 km./sec. are measured with a considerable precision.

If the observed shift of the spectral lines of a star is corrected for the motion of the earth, one finds the velocity of the star with respect to the sun. In the case of many spectroscopic binaries, the determination of the elements of their orbits would be wholly impossible if the motion of the earth were not taken into account.

The velocity of a point of the earth's surface due to the rotation is much smaller than the translational velocity. Even for a point on the equator, it amounts to no more than 0·46 km./sec. The displacement of a spectral line corresponding to this is, for yellow light, about 0·009 Å.U., 1/660 part of the distance between the D-lines. This can scarcely be observed. If it were somewhat greater, one would see that the lines in the solar spectrum lie somewhat more towards the violet at sunrise than at sunset. It must be remarked that the consequences which one draws from Doppler's principle would remain true whatever might be the state of motion existing in a medium surrounding the earth. The question only is whether two successive vibrations emitted by the source take equal or unequal times to reach the slit of the spectroscope.

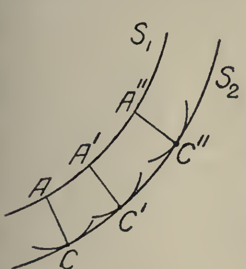

FIG. 1.

2. HUYGENS'S CONSTRUCTION.—In the second place, the propagation of waves and rays of light may be modified by a motion of the system, a modification that can be found by means of Huygens's construction. Let S_1 (Fig. 1) be the wave-front, *i.e.* the surface that is reached at a certain time t by a vibration emitted by the source at some previous instant. Then, around each point A, A′, A″ . . . of S_1 one can describe the elementary wave formed in a time dt. The surface S_2 tangential to them all will be the new position of the wave-front. The lines AC, A′C′, . . ., joining the centres of the elementary waves to the points where they are touched by S_2, are elements of rays, *i.e.* of the lines which determine the lateral limitation of beams of light. The velocity of a ray is given by

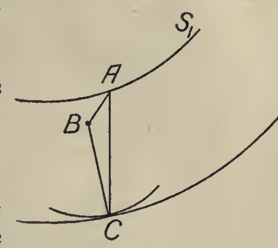

FIG. 2.

$$u = \frac{AC}{dt}, \quad . \quad . \quad . \quad . \quad . \quad (1)$$

and the course of a ray of light s between two given points A and B is determined by the condition that

$$\int \frac{ds}{u} \quad . \quad . \quad . \quad . \quad . \quad (2)$$

is a minimum (Fermat's principle).

This general method can be applied to the case of ether moving through the diagram with respect to which one wants to know the propagation of light. The elementary wave around a point A (Fig. 2) is a sphere with radius cdt (c velocity of light in ether), but drifting along with the ether. The centre of the sphere will be at B, if AB is in the direction of the velocity v with which the ether moves across the diagram and has the length vdt. From the triangle ABC one finds, if θ is the angle BAC between the velocity of the ether and the ray AC, and if terms of the order $(v/c)^2$ are neglected,

$$\frac{ds}{u} = \frac{ds}{c} - \frac{v}{c^2}\cos\theta ds. \quad . \quad . \quad . \quad (3)$$

The figure also shows to what extent the ray AC deviates from the normal BC to the wave-front.

3. STOKES'S THEORY OF ABERRATION.—In this theory it is supposed that the ether is set in motion by the earth, like an incompressible fluid, the velocity of the ether at any point of the surface being equal to the velocity of the earth. At some point P just outside the region where there is an appreciable velocity of the ether, the light coming from some star S will have its wave-front at right angles to PS. The above construction gives the direction of the ray, *i.e.* the direction in which the star is observed; the result agrees exactly with that of the well-known elementary theory of aberration. Stokes further supposes that the motion of the ether is irrotational, so that v depends on a velocity potential. In this case (3) shows that (2) may be replaced by $(1/c)\int ds$ plus a term that is independent of the path; the ray of light is therefore a straight line, and the ordinary

[1] Lecture delivered at University College, University of London, on May 17.

theory of aberration not only holds for the point P, but also for the point where the ray reaches the surface of the earth.

Stokes's theory cannot, however, be maintained, because the two assumptions that there is a velocity potential and that all over the surface the ether has the velocity of the earth contradict each other.

4. Ether Whirls.—It can be imagined that a rotating planet is surrounded by a whirl in the ether. If definite assumptions are made concerning the distribution of velocity in this whirl, one can determine the deviation of a ray passing through it and the amount of diurnal aberration thus produced.

There is another phenomenon still by which one could detect an ether whirl. If the planet Jupiter were surrounded by a whirl, there would be a deviation that could be observed in the case of the occultation of a star, and that is found to be quite appreciable if plausible assumptions concerning the extension of the whirl be made. Nothing of the kind has ever been observed. This speaks in favour of the hypothesis that the ether is not set in motion by the planet.

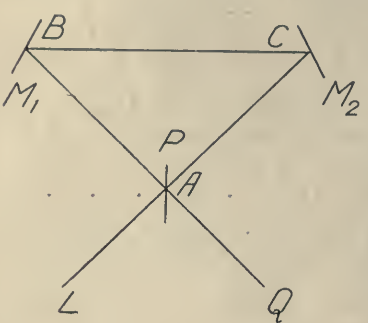

Fig. 3.

5. Fresnel's Theory of Aberration.—Fresnel assumed that the earth is absolutely permeable to the ether, so that it can pass through the ether without in the least setting it in motion. So far as the subject of this lecture is concerned, this assumption leads to the same results as the theory of relativity. The annual aberration is now immediately explained by what was said in § 3. As to the daily aberration, it is determined in the same way as the annual aberration by the motion of the observer. If an astronomer placed at a point on the equator observes a star situated in the plane of that circle, at an altitude h, the aberration amounts to $0{\cdot}32'' \times \sin h$. It would be possible to observe it if the distance of two stars far apart could be measured to within $0{\cdot}1''$. If, for example, two stars A and B in the plane of the equator follow each other in their daily motion at a distance of 60°, their distance will be diminished by $0{\cdot}16''$ when A has reached the zenith, and increased by the same amount when B has reached that point. In reality, however, the existence of the diurnal aberration has not been proved, though astronomers correct their observations for it.

6. Michelson's Interference Experiment.—Prof. Michelson has devised an experiment in which two rays of light propagated in opposite directions along the sides of a great triangle ABC (Fig. 3) in a horizontal plane are made to interfere; M_1, M_2 are mirrors, P a dividing plate of glass; the course of one ray is LACBAQ, and of the other LABCAQ.

In general, let L and Q be any two points having a fixed position in the figure, which is attached to the earth. The ether (supposed not to share the earth's rotation) has a motion through the diagram, consisting in a rotation about the axis of the earth. From what has been said in § 2, one can deduce the time that is required for the passage from L to Q. Let s be the course of the ray if there were no rotation, s' the actual course. One has to calculate the value of (2) for s', but if one neglects terms of the second order, one can substitute for it the value for the path s, because the integral is a minimum for s'. The influence of the earth's rotation is given by the integral of the last term in (3), and is found in the case of Fig. 3 to be proportional to the area of the triangle ABC, to the angular velocity of the earth, and to the sine of the geographical latitude. The effect would be of equal magnitude but of opposite sign for the two interfering rays, and so the position of the interference fringes will be slightly changed by the rotation of the earth. It may be hoped that it will be possible to observe the effect by a suitable method of observation.

7. An Imaginary Experiment.—Suppose two parallel metallic wires (perfect conductors), such as are used in Lecher's experiment, to be placed round the equator of the earth, each forming a closed circle. Let standing electromagnetic waves be produced between these wires. One may confidently expect that the loops and nodes will travel around the earth from east to west in 24 hours, and this can be considered to be a proof of the earth's rotation.

If the statement that the earth rotates is to have any meaning one must assign some system relatively to which the rotation takes place. If the imaginary experiment were performed with the result just mentioned, one could say that the earth rotates (1) relatively to the loops and nodes, (2) relatively to a system of co-ordinates in which light is propagated in straight lines with the speed c, (3) with respect to the stationary ether in which the loops and nodes have their seats, or (4) with respect to the fixed stars by the influence of which the position of the loops and nodes is determined. (Mach, Einstein.)

A Large Refractor for Johannesburg.

By Frank Robbins.

Twenty years ago, and soon after the close of the Boer War, the South African Association for the Advancement of Science petitioned the Transvaal Government for the establishment of an observatory for the sciences of meteorology and astronomy. The reply was immediately favourable as regards meteorology, but it was not found possible to organise an astronomical department for some half-dozen years or so. In the meantime, by loan or by gift, a few instruments were obtained, and quite soon attention was forcibly directed to the very exceptional climate and sky of Johannesburg by means of work actually done there by the aid of a modest 9-inch refractor. In consequence, early in 1909 the Minister for Lands

made provision in his estimates for the erection of a visual refractor of 26 inches clear aperture, and a contract with Sir Howard Grubb and Sons, Ltd. was signed in November of that year. Discs for the objective were ordered at once from France, but the production of optical glass of that size is a slow and uncertain process, and in 1912 efforts were made to obtain a supply from Messrs. Chance Bros. and Co., Ltd., of Smethwick, near Birmingham.

Trials and disappointments followed, parallel and in series too. At this time Sir David Gill, the designer of the telescope, had inspected the equatorial and reported "Nearly complete and exceedingly satisfactory"—this was in the summer of 1912. There followed two years full of hope passed in fresh efforts and experiments. Then the Great War put a stop to everything. . . . The Armistice came at last, and when the smoke of battle cleared away it was found that the Admiralty had silently transferred Sir Howard Grubb's workshops from Rathmines, near Dublin, to St. Albans, and there in the confused heaps of material, tools, patterns, periscopes, range-finders, and waste, lying on the new workshop floors, it was said the famous telescope was lying dismembered and for the most part unrecognisable.

It was necessary to start again, not quite from the beginning but very nearly so, and this necessitated conferences, new estimates, and references to Pretoria, but finally order arose out of chaos. Fresh contracts were made in November 1922, and in the following March Messrs. Chance Bros. reported complete success. On their invitation a few astronomers journeyed to Birmingham to view these long-desired discs, and there the visitors experienced moments, nay minutes of tension. The room containing this precious optical glass proved unsuitable for the examination, so two workmen carried the flint disc weighing some 240 lbs. in their four bare hands through a narrow doorway across an uneven floor, wending their way between great blocks of glass into another room. Perhaps it was not as dangerous as it looked, but to the interested spectators it seemed a passage perilous, where the labour of thirteen years might have been lost by an unlucky step.

These two discs, when tested for striæ and annealing, satisfied the optical expert, and they were taken to St. Albans, where the rough grinding of the flint is proceeding as shown in Fig. 1. To the objective it is intended to give the form now generally familiar to astronomers: a double convex crown fronts the stars and is followed at a distance of some six inches by a double concave flint, the fourth surface being of extremely long radius. In its mounting a close-fitting sliding band will make it possible to clean either or both the inner surfaces, and here it has been essential to pay special attention to the complete exclusion of dust, of which Johannesburg easily obtains its share. The rough discs measured $26\frac{3}{4}$ inches, and are to yield a finished objective of 26 inches clear, with a focal length of, say, 35 feet, giving a ratio just over 16.

The dome for the telescope has been ready and in position for so long that its appearance in any photograph of the outskirts of Johannesburg must be quite familiar to many. A good photograph of the whole instrument on its equatorial as it stands in Fleet Works, St. Albans, cannot be obtained, and yet it is probably the most frequently photographed telescope in the eastern hemisphere; since Christmas last, views of it have appeared in two of London's leading newspapers, but each time it has been ascribed to Russia, and on the first occasion it was even described as the largest telescope in the world.

Fig. 2 shows the view from the south-west of the heavy castings for the stand with the polar axis carrying the right ascension circle at its lower (north) end. Most of the tube is visible, with its central cube and the extension for the counterpoise. Fig. 3 is the breech-piece with photographic plate-holder. It shows also the 4-inch finder of 60 inches focal length. This is provided with either a variable bright field or with bright wires as desired for the particular work in hand. Several of the circular weights are to be seen the removal of which will make it possible to fit a spectrograph if it is so desired at any time in the future. These weights equal in all 370 lbs. The motive power for the driving clock is a weight which falls a quarter of an inch every ten seconds—the rewinding is automatic and electric. The weight of the moving parts amounts to more than five tons, but the roller bearings supplied and the carefully equal distribution of the mass make it easy for the observer to shift this load with one hand.

Fig. 1.—Flint disc.

The process of finding a faint star with this instrument is not quite as ordinarily obtains — it is more simple. The declination clamp is released, and the required declination reading is obtained; the instrument is then re-clamped. Now, because the right ascension circle is clock-driven, it constantly indicates

the local sidereal time. The right ascension clamp is released and the telescope shifted until the reading microscope shows the right ascension of the star. The right ascension is then clamped and the dome the quick motion in right ascension. The slow motion is controlled by the observer alone, who also holds in his hand means of adjusting the clock rate. Both co-ordinates of a star are read very easily from the eye

FIG. 2.—Equatorial with steel tube.

opened. The rising floor has a range of twelve vertical feet—it is not circular, and in azimuth it extends over 120° but always opposite the dome opening; for example, end, where there is a choice of three breech-pieces—one visual with four oculars, a second with a Repsold micrometer, and a third the photographic, made by

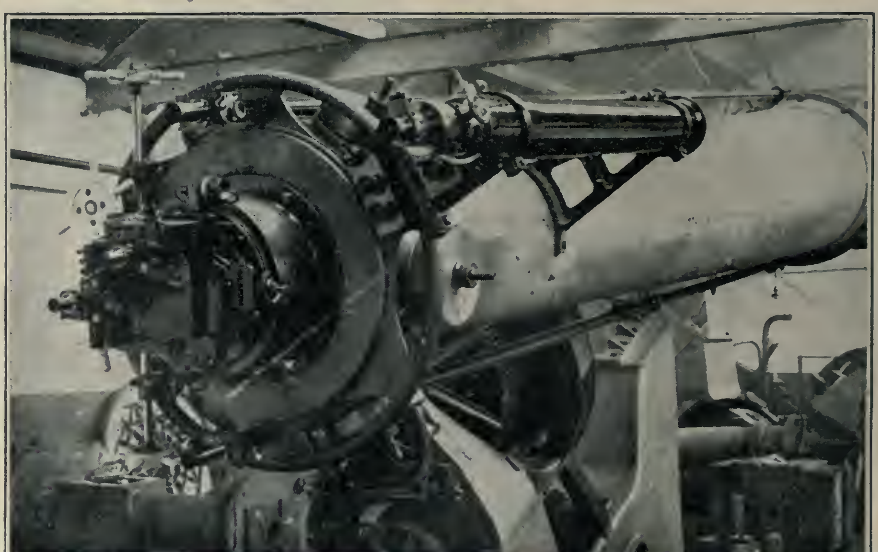

FIG. 3.—Eye-end 26-inch refractor.

when the telescope is pointing to N. 270° E. the rising floor or platform lies between N. 30° E. and N. 150° E. Observers being scarce, provision is made to save them from walking over the edge. In actual work an assistant will stand at the north end of the base and in charge of Adam Hilger to a specification and design by Sir David Gill. No digging for a foundation is required; the pier will be bolted directly to an outcrop of solid rock.

It remains to add a few words on the environment of this much-needed addition to the meagre list of large

telescopes south of the equator. Every one has heard of the Witwatersrand as the source of much of our gold. This range of hills lies in latitude 26° 11′ south, just north of Johannesburg, and here, at an altitude of 5925 feet, a thousand miles from Cape Town, and 240 miles from the sea, is the observatory. Antares is four minutes of arc south of the zenith, and is the only clock star required. The average height of the barometer is 24·35 ins.—one-sixth of the atmosphere is below and the part remaining is here less subject to vagary than in almost any other part of the habitable globe. The climate is remarkably sunny, and the sky is free from cloud to a very high degree. Astronomical observations are possible on 300 or more nights in each year; on 200 of these one could observe for ten hours continuously.

Think what this means; work can be planned months ahead with a certain assurance of favourable skies. There are no nights wasted watching for a possible break in the clouds, which, coming, is gone before it can be utilised, but good observing weather in quantity, the incidence of which can be predicted 99 times out of a 100. Cloudiness on the average equals 30 per cent., and even in the rainy season seldom exceeds 44 or 46 per cent. Humidity for the year is 57 per cent., January 71 per cent., July 42 per cent. Rainfall 25 to 30 inches, but there are only 85 wet days and not more than 190 wet hours. Of course there is a drawback: high easterly winds with dust; and such dust—clouds of it, equal in density to a fog, but not more than two or three days in a year are as bad as this. The seeing is exceptional—not optically perfect perhaps, but so nearly ideal that the fame of its quality is spreading abroad, and rumours are heard of northern observers intending to enlarge and complete their researches by a sojourn in the Union of South Africa.

Current Topics and Events.

WE have on several occasions expressed regret that no provision seemed to have been made for the display of achievements of pure science and their relation to industrial and Imperial development at the British Empire Exhibition to be held next year. We are glad, however, now to be able to announce that at the request of the Exhibition authorities the Council of the Royal Society has appointed a Committee to organise a central exhibit to illustrate the fundamental principles of certain departments of pure science, with special reference to the share taken in developing those principles by the Empire. A small sum of money has been placed at the disposal of the Committee and space allotted in the Central Pavilion. The Committee, which is a strong one, represents all branches of science. Sir Richard Glazebrook is chairman, with Sir Herbert Jackson and Mr. F. E. Smith as vice-chairmen. Mr. Woolcock, the chairman of the Association of British Chemical Manufacturers, who is taking the leading part in the organisation of the chemical exhibit, has become a member of the Committee.

THE Empire Cotton Growing Corporation has recently been considering the necessity for organised research at the universities and colleges of Great Britain, and has decided to offer retaining grants to certain universities where highly specialised research is already going on. The Imperial College of Science and Technology, South Kensington, has accordingly been offered the sum of 1000*l.* a year for a period of five years from October 1, the money to be devoted to plant physiology and plant pathology in the Department of Botany. The research work will be undertaken in the new Botany Building, recently opened by the Duke of Devonshire, to which the Rubber Growers' Association of the City of London subscribed about 30,000*l.* about two years ago. These gifts are tangible evidence of the value which tropical agriculturists attach to the important research work which is being undertaken at the Imperial College, especially in connexion with plant physiology and pathology, under the direction of Profs. J. B. Farmer and V. H. Blackman.

JULY this year has established a weather record for temperature, and in many places the thermometer has exceeded records for many years past, not only for July but also for any part of the summer. The hot spell was fairly established on July 5, when at Kensington and Greenwich the sheltered thermometer rose to 84° F. On July 6 the temperature at Kensington was 87° F., and at many health resorts it was 85° F. At Greenwich on July 7 the thermometer in the shade registered 90° F., and the solar radiation temperature was 163° F. The severe thunderstorms and torrential rains so prevalent over the country on July 9 and 10 had little effect in reducing the temperature, and from July 11 the heat became more intense. On July 12 the thermometer at Andover registered 94° F., and on July 12 and 13 the temperature at Kensington was 92° F., while the minimum night temperature registered on both mornings was 68° F. At Bath on July 12 and 13 the thermometer registered 93° F. and 92° F. respectively. On the night of July 12-13 the minimum temperature was 71° F. at Hastings and Brighton. At Kew the maximum temperature was 80° F. or above for ten consecutive days, and 91° F. recorded on July 13 is a record for July; while on the same day 96° F. at Camden Square is the highest temperature reported to the Meteorological Office during the warm spell. These temperatures fall somewhat short of the London readings during the abnormal summer of 1911, when 100° F. was recorded at Greenwich and 95° F. at Kew on August 9. A new type of pressure distribution set in over the British Isles on July 14, and a drop of temperature occurred in most parts of the country.

THE following elections to Beit Memorial Fellowships for Medical Research have been made, the general subject and place of research being given after each name:—*Senior Fellowship*: Dr. D. Keilin: the life-history of parasitic Protista and the physiology of parasitic Metazoa, at the Molteno Institute for Research in Parasitology, University of Cambridge. *Fourth Year Fellowship*: Dr. Katherine H. Coward: the processes of metabolism, nutrition and growth of

young animals, particularly with reference to the so-called deficiency diseases such as rickets, at the Biochemical Laboratory, Institute of Physiology, University College, University of London. *Junior Fellowships*: Dr. J. M. H. Campbell: Oxygen consumption and pulmonary ventilation during and after work in chronic heart and lung disease; total metabolism and "efficiency" of work in these and other diseased conditions; changes in the capillary circulation in the skin in certain chronic nervous diseases, at the Department of Physiology, Guy's Hospital, London. Mr. C. G. Lambie: Influence of insulin upon fat and protein metabolism; observations upon the fate of the sugar which disappears from the blood in hypoglycæmia produced by insulin, at the University of Edinburgh. Mr. W. K. Slater: Determination of the molecular weight and heat of combustion of glycogen; an investigation of cell mechanism under anaerobic conditions, in the Physiological Laboratory, University of Manchester, and the Institute of Physiology, University College, London. Miss D. S. Russell: The relation of renal efficiency tests to the morbid anatomy and histology of kidneys, at the Pathological Institute of the London Hospital. Mr. C. P. Stewart: Investigation of the methods of isolation and chemical constitution of thyroxin; the liver perfusion of substances related to histidine, in the Department of Medical Chemistry, University of Edinburgh. Mr. H. J. Channon: The study of certain fundamental dietary factors in the nutrition of living organisms, at the Institute of Physiology, University College, London. Mr. W. Smith and Mr. L. B. Winter: Investigations on general metabolism in health and disease, with special reference to the metabolism of carbohydrates; search for alternative sources of insulin, notably from yeast, at the Biochemical Laboratory, University of Cambridge. Miss D. B. Steabben: Investigation of the mechanism of response to injection of colloidal substances, at the Lister Institute of Preventive Medicine, Chelsea Gardens, S.W., and King's College (London) Physiological Laboratory. Mr. C. S. Hicks: Investigation of the causation of goitre from a biochemical point of view, such as a close examination of the relationship of iodine in foods to the incidence of goitre; the chemistry and pharmacology of substituents in the thyroxin molecule, from the point of view of the physiological action of thyroxin, at the Balfour Laboratory, University of Cambridge.

The Court of the Salters' Company has appointed Prof. A. Smithells to be director of the Salters' Institute of Industrial Chemistry.

We regret to announce the death on July 15 of Sir Henry Hoyle Howorth, F.R.S., a trustee of the British Museum since 1899, at the age of eighty-one.

The diamond jubilee meeting of the British Pharmaceutical Conference and a meeting of the International Pharmaceutical Federation will be held in London on July 23-27.

The Royal Danish Academy at its last annual meeting elected the following honorary foreign members: Prof. Albert v. Le Coq, of Berlin, Profs. Charlier, J. Forssman, and C. M. First, of Lund, Dr. F. A. Bather, of the British Museum, and Prof. F. O. Bower, of Glasgow.

At a recent meeting of the Institution of Electrical Engineers the following officers were elected:—*President*: Dr. A. Russell; *Vice-President*: Sir James Devonshire; *Hon. Treasurer*: Mr. P. D. Tuckett; *Ordinary Members of Council*: Mr. J. M. Donaldson, Dr. W. M. Thornton, Colonel T. F. Purves, Mr. G. W. Partridge, Mr. P. Rosling, and Mr. S. W. Melsom.

It is announced in *Science* that on his retirement through ill-health from the directorship of the Mount Wilson Observatory Dr. G. E. Hale has been appointed honorary director. Dr. Hale will remain in charge of the general policy of the observatory, and Dr. W. S. Adams, at present assistant- and acting-director, has been appointed director in charge of operations.

At a quarterly meeting of the council of the Royal College of Surgeons of England, held on July 12, Sir John Bland Sutton was elected president and Sir Berkeley Moynihan and Mr. H. J. Waring were elected vice-presidents for the ensuing year. Among the elections made were the following: Mr. H. E. Griffiths, Mr. V. B. Negus, and Mr. C. P. G. Wakeley to be Arris and Gale lecturers, Prof. S. G. Shattock to be Erasmus Wilson lecturer, and Sir Arthur Keith to be Arnott demonstrator.

The Minister of Agriculture and Fisheries has appointed the following departmental committee to inquire into the operations of the Fertilisers and Feeding Stuffs Act, 1906: Lord Clinton (Chairman), Mr. E. Richards Bolton, Mr. E. G. Haygarth Brown, Dr. Charles Crowther, Mr. T. Kyle, Mr. B. S. Miller, Mr. G. Stubbs, Dr. J. F. Tocher, and Dr. J. A. Voelcker. The committee is to advise whether any, and if so what, amendments are necessary in order to render the execution of the Act more economical and effective, and to report accordingly. Mr. H. J. Johns, of the Ministry of Agriculture and Fisheries, 10 Whitehall Place, S.W., has been appointed secretary to the committee.

Among the subjects discussed at the recent International Navigation Congress at Westminster on July 2–6 were the latest improvements in regard to signalling at sea and on the coast. Fourteen reports were submitted to the Congress, covering the current practice in Great Britain, Belgium, France, Holland, Italy, Japan, Russia, Spain, Sweden, and the United States. Reference was made to experiments carried out by Trinity House, in 1921, in connexion with synchronous signalling, in which two types of sound-transmitters were used—one a standard submarine bell, and the other a Fessenden oscillator, in conjunction with a wireless transmitter. The signals received from these were of such a character as to enable the distance to be calculated of objects invisible in fog, but within submarine sound range. A wireless installation, lately erected at Inchkeith in Scotland, was mentioned as affording facilities for experimenting with direction messages to vessels equipped with a simple type of receiver gear. The most important advance in light-

house work in the United States has been the establishment of radio fog signals. A plea was entered for the international adoption of some system of underwater signals, by which vessels in an area of reduced visibility could transmit information as to their courses to other vessels in the vicinity, as well as obtain the bearings of such vessels. The radio compass and position-finder now enable ships to approach the coast in thick weather. It remains to provide means to ensure the safety of vessels coasting and entering port. The feeling was expressed that the subject of marine signalling was so important as to claim a larger share of the time of the next Congress.

On July 4 Professor Dr. Ernst Beckmann completed his seventieth year. He was an apothecary originally, and changed over to the study of chemistry in 1875 under Kolbe in Leipzig. After a short stay at the Technical Highschool in Braunschweig he went to the University of Leipzig in 1884, where he worked first with Johannes Wislicenus and later with Wilhelm Ostwald. It was about this time that Beckmann made the observation that ketoximes are transformed by pentachloride of phosphorus into acid amides. This Beckmann transformation has shown itself to be a very productive reaction for the investigation of the stereo-isomeric nitrogen compounds. At the same time Beckmann elaborated the well-known methods for the determination of molecular weights by observation of lowering of the freezing point and rise of the boiling point of solutions. The use of Beckmann's apparatus is now widespread, as well as the Beckmann thermometer employed in these operations, which combines accuracy to one-thousandth of a degree Centigrade with a very simple regulation for the most varied ranges of temperatures. After having been for a short time at the universities of Giessen and Erlangen, Beckmann returned to Leipzig in 1897, and remained there as director of the laboratory for applied chemistry until 1912. During this time he showed great activity in numerous investigations in pure chemistry, foodstuffs, and drugs; further, he constructed the burners fitted with sprays which allow of continuous working with coloured flames for spectroscopic and other optical work. In 1912, Beckmann undertook the organisation of the newly founded Emperor William Institute for Chemistry in Dahlem, where Willstätter, Stock, O. Hahn, and Lise Meitner have done much of their work. He resigned from the directorship of this institute in 1921, but is still untiring in research and literary work.

The rise and growth of scientific and technical journalism is one of the most characteristic features of modern civilisation. Some day the upward trend of this movement must show a flattening tendency; but of the approach to this phase there is at present little evidence. The "List of Serials received in the Library of the U.S. Department of Agriculture" (Washington: Government Printing Office), exclusive of U.S. Government and State Agricultural College and Experiment Station Publications, which has recently been received, includes no less than 5586 distinct serials. If the excluded serials were added o the above figure and the publications currently received by the U.S. Weather Bureau were also thrown in, a grand total of at least 7000 serials would be recorded. All these serials, of course, are not exclusively devoted to agriculture, but they have, at any rate, been collected with the view of the furtherance of the work of the Department. As regards the purely agricultural serials, the list is practically a bibliography of the subject. The auxiliary sciences are adequately but less completely represented. The list, which is an 8vo volume comprising 358 pages, is divided into four parts. Parts 1 and 2 form a register of the entire collection. Part 3 is an admirably compiled subject classification of the serials set forth in parts 1 and 2. This part includes the U.S. Government and State publications. Part 4 is a regional distribution of the data contained in parts 1 and 2. The list is admirably compiled and clearly printed. The librarians of the Department are to be congratulated upon its production.

Referring to Dr. J. S. Owens' letter in Nature of June 23, p. 848, regarding the haze overlying southern England on Derby Day, Mr. F. R. Farquharson states that he made an exposure on the course, using the widest aperture of the lens on a Kodak film, when the horses suddenly appeared out of the mist barely a hundred yards away. The result when developed showed over-exposure, thus proving that the mist had not that light-stopping power common to the normal London mist. Dr. J. S. Owens writes: "The obstruction caused by a haze depends not only on its density but also on the length of path of the light through the haze. The distance between camera and object was short and thus obstruction correspondingly small, while it is probable also that the vertical thickness of the haze was small and thus plenty of light penetrated. Anti-cyclonic weather, which is often accompanied by an inversion of temperature gradient a little above the ground, provides suitable conditions for a shallow dust haze. The dust being unable to penetrate the 'lid' formed by the temperature inversion, may travel for great distances along the ground obstructing visibility of objects at a distance, but having little effect on the quantity of light reaching the ground from the sky. In a London smoke fog both the number of particles per c.c. and their size are usually greater, while the thickness of the layer of fogs is probably also much greater than in a haze such as that on Derby Day."

Mr. T. H. Digges La Touche, who is so well known by his published work in connexion with the Geological Survey of India, has prepared the catalogue and subject-index of literature added to the library of the Geological Society of London during the years 1915–1919. This volume of 545 closely printed pages fills the gap in the valuable lists issued by the Society, which are now complete to the end of 1922. Its price (10s.) is moderate, and for libraries the collection of the records for several years into one continuous series facilitates reference. The subject-index, occupying half the volume, is a monument to the careful reading and judgment of Mr. Digges La Touche, and it must be remembered that, for the period named, the work represents very fairly the

geological literature of the world. We cannot find here lists of the publications of geological surveys; these are indexed under their authors and the districts with which the memoirs deal. Maps separately issued are not regarded as "literature"; but, under the heading "Maps," there is a very useful list of those included, and often concealed, in printed papers, with indications of their scales.

In connexion with the mechanism whereby pollen is able to induce hay fever, a correspondent has suggested that possibly the pollen grains in the presence of moisture on the mucous membranes might protrude their pollen tubes; these might penetrate the mucous membrane. A view somewhat similar was developed by Blackley half a century ago in his famous "Experimental researches on the causes and nature of Catarrhus aestivus." He showed that neither the size nor the nature of the covering of the pollen can be the essential cause of hay fever, but from prolonged observations he believed that the moisture on the mucous membrane might cause the pollen to swell and to protrude its tube into a mucous gland. While this might explain some of the initial phenomena in an attack of hay fever, he was strongly of opinion that the obnoxious element of pollen was the granular matter in the centre, a view universally accepted to-day.

Our Astronomical Column.

Large Meteor.—In strong twilight on the evening of July 11 a fine meteor was seen at $9^h\ 9^m$ G.M.T., by Mr. E. W. Barlow of Wadhurst, Sussex, who considered the object as bright as Venus at its best. The nucleus was pear-shaped and bluish, and a red train followed it along an arc of about 10°. The duration of flight was 4 seconds and the path from 95 Herculis to η Ophiuchi.

Mr. E. H. Smith of Hanwell, W., also saw the object and describes the path with reference to the stars Altair and Antares. The height of the meteor was about 66-54 miles over the English Channel; length of path 90 miles, and velocity about 22 miles per second.

The fireball was also observed by the Astronomer Royal and by Dr. Crommelin at the Royal Observatory, Greenwich, and they give the azimuth of the end point as 15° W. of south.

The Spiral Nebulæ as Dust-Clouds.—Mr. J. H. Reynolds discusses in Mon. Not. R.A.S. for May the recent suggestion of Prof. Lindemann that the spirals are dust-clouds expelled from the Galactic system by radiation pressure, and shining by reflected starlight. He gives a diagram of the distribution of the spirals, and of their radial velocities, determined by Prof. Slipher. The data as regards size, inclination, and radial velocity appear to fit in fairly well with Lindemann's theory, if one adopts the eccentric position of the sun in the Galaxy, as given by Prof. Shapley's determination of the distances of globular clusters. The spirals nearest to the Galactic centre would have the highest velocities, but would appear small to us, owing to distance. Those nearest to us would appear large, but would have small radial velocities, their motion being nearly across the line of sight. There is one feature of the spirals, however, that Mr. Reynolds regards as negativing the theory of their shining by reflected starlight. This is the dark absorption stripe which is seen to cross the centre of many of the spirals that are seen nearly edgewise. On the reflection hypothesis, this should be bright and not dark; its presence seems to prove that the illumination of the spirals comes from within them. Some years ago Mr. Reynolds put forward the view that the spirals were shining by reflecting the light of some bright body in their centre, basing this on measures of the relative brightness of different regions. He now repeats this suggestion, and adds that it may be possible for the condensed matter in the middle of the spiral to give a spectrum of type F or G, without being in a stellar state. He quotes in support some recent experiments on the spectra given by exploded wires.

Stars in the Milky Way and at the Galactic Pole.—The Harvard College Circ. No. 242 contains a very interesting comparison of a Milky Way field with one at the South Galactic Pole made by Mr. Solon I. Bailey. The aim of such investigations is not only to give an estimate of the total number of stars that exist or rather can be photographed, but also to form an idea of their distribution in space. Star gauges were made by the Herschels a century ago, but since then studies of the distributions of stars have been completed by Argelander, Seeliger, Pickering, Celoria, Kapteyn, Chapman and Melotte, and others. It was generally deduced that there were only twice as many stars in the Milky Way as elsewhere up to about magnitude ten, although Herschel's counts gave a maximum of about 20 times as many stars in the Galaxy as at the Galactic poles. An increasing Galactic concentration with decreasing apparent brightness was shown by Kapteyn, and a similar but less rapid degree of concentration was deduced by Chapman and Melotte. Mr. Bailey discusses photographs taken with the 24-inch Bruce photographic telescope at Arequipa, Peru, the longest exposures showing stars fainter than the nineteenth magnitude. He gives a very instructive table indicating the relation of length of exposure to limiting magnitudes photographed, showing that as the stars become fainter, longer and longer exposures have to be made to gain every extra magnitude. Selecting a square degree area in Sagittarius in the Galaxy, one of the richest star fields of the Milky Way, and comparing this with the similar area at the South Galactic Pole, he obtains the following counts:

Exposures. m.	s.	Limiting Magnitudes.	Number of Stars. Galaxy.	Pole.	Ratio.
0	1	10·1	13	5	2·6
0	3·3	11·2	47	13	3·6
0	10	12·4	111	29	3·8
0	30	13·5	349	62	5·6
1	29	14·6	1,945	104	18·7
4	27	15·6	9,160	151	60·7
13	20	16·5	21,895	225	97·3
40	0	17·4	36,260	359	101·0
120	0	18·3	57,130	494	115·6
360	0	19·2	61,595	551	111·8

It will be seen that, up to about magnitude 10, the number of stars in the Milky Way is about 2·5 times that at the pole. After magnitude 13, the ratio increases with great rapidity, until at about the 17th magnitude the ratio is more than 100. If the stars were everywhere as dense as in this part of the Galaxy their number would be 2·5 billions, while if the density were that at the pole, their number would be 23 millions.

Research Items.

DEPOPULATION OF PRIMITIVE COMMUNITIES.—Mr. J. H. Hutton, whose monographs on two branches of the Naga Tribes in Assam have been received with much favour by ethnologists, reviews in *Man in India* (vol. 2, No. 4) the work of the late Dr. Rivers on depopulation in Melanesia, in the light of his experiences in Assam. He notes that, as in the case of the Kava of Melanesia, the influence of missionary societies in Assam, who discourage the use of the mild rice beer, is driving their converts to opium. The appearance of consumption in recent years in the Naga hills may be attributed to the wearing of European clothes, which is also responsible for the spread of dysentery, itch, and yaws. The absolute prohibition of head-hunting has led to serious interference with all sorts of dependent activities, and ultimately leads to a total lack of interest in life, and so to the limitation of families, or even to the total refusal to procreate children. These facts, which corroborate the conclusions of Mr. Henry Balfour in the presidential address recently delivered before the Folklore Society, deserve the serious attention of all those who are responsible for the welfare of primitive societies.

BRONZE AGE WEAPONS IN THE HULL MUSEUM.—In *The Naturalist*, No. 795, for April, Mr. T. Sheppard reports further valuable additions to the collections in the Hull Museum. Some of these pieces formed part of the Scarborough hoard, of which twenty-three are now in the museum. The new examples include some interesting axes and palstaves. An analysis of one of the axes by Prof. Cecil H. Desch shows that it contains 80·25 per cent. of copper, 16·39 per cent. of tin, and minute quantities of lead, nickel, and sulphur.

CONTRACTION AND DILATATION OF BLOOD-VESSEL.—Special interest has been aroused by the work of the Petrograd physiologist Kravkoff, who is already known for his work on the contraction and dilatation of the blood-vessels of surviving organs. Kravkoff usually employs rabbits' ears, which retain their vitality for a long time. Even after keeping these organs for several days and weeks he obtained a definite reaction with adrenalin. In his investigation he devised two methods for preserving the ears. As the ears usually perish from infection contracted at the cut surface, he seals that end by dipping the excised ears into a vessel with molten paraffin. When the paraffin solidifies the ears stand up in the vessel like plants in a flower-pot, and in this way the vital properties of the vessels are preserved for a long time. The second method is that of drying. The ears are dried in an evacuated desiccator over sulphuric acid until the moisture content is 5-6 per cent. Such preparations can be kept for about three months, and after soaking they respond to chemical stimuli. In this way also organs of higher animals show parabiosis after drying. It was also found convenient to employ human fingers, from amputations or later from corpses, for the study of the blood-vessels. These organs are just as sensitive in responding to poisons and adrenalin and can be utilised as anatomical specimens as well. They can also be preserved and dried. These surviving organs also possess the property characteristic of living animals, that their skin reacts to cantharadine, producing a focus of local inflammation with a blood-vessel reaction and tissue œdema.

THE ALLANTOIC PLACENTA OF MARSUPIALS.—One of the results of the visit of the British Association for the Advancement of Science to Australia in 1914 was the establishment of a committee to promote the collection of material for the study of the marsupials, with special reference to their embryology, a task rendered imperative by the rapid extermination of the native fauna. The principal part of the work of this committee was entrusted to Prof. T. Thomson Flynn of the University of Tasmania, who gives us the first instalment of his embryological results in a memoir on the Yolk-Sac and Allantoic Placenta in Perameles, published in the current number of the *Quarterly Journal of Microscopical Science* (vol. 67, part 1). It was in Perameles that Prof. J. P. Hill first discovered the existence of an allantoic placenta in the supposedly "non-placental" marsupials. Prof. Flynn confirms and extends Hill's observations, and endeavours, apparently with success, to reconcile the supposed discrepancy between the development of the marsupial allanto-placenta and that of the primitive eutherian type, maintaining that the difference between the two is one of degree rather than of kind. He draws a close comparison between the early stage of the allanto-placenta in Perameles and that of the dog, and holds that both can be derived from a common ancestral condition. He agrees with Hill in attributing the absence of an allantoic placenta in the majority of the Marsupialia to degeneration.

THE PLEISTOCENE OF NORTH AMERICA AND ITS VERTEBRATES.—The Carnegie Institution of Washington has issued as its Publication No. 322 a substantial volume by Mr. O. P. Hay on "The Pleistocene of North America and its Vertebrated Animals from the States east of the Mississippi River and from the Canadian Provinces east of longitude 95°." By the author, who is obviously a thoroughgoing glacialist, "the Pleistocene is regarded as being equivalent to what is known as the Glacial Period," and is divided by him into nine stages, five glacial and four interglacial, while the Blanco is held to belong to the upper, or uppermost, Pliocene. His Pleistocene is, therefore, obviously not quite homologous with the period that passes under that name with British geologists. The various vertebrates are first dealt with mostly in groups, cetaceans, mastodons, etc., but sometimes by individuals, as in the case of three species of Elephas; and their occurrences in each State, county by county, is recorded and charted on maps. To this succeeds a section on the Pleistocene geology of the several States, with the assemblages of animals found in the various beds. Whether the value of all this painstaking work will prove commensurate with its bulk of 500 octavo pages, time alone can show. The author's conclusions as to the dates of advent and disappearance of the different forms that are summed up in the table on pp. 14-15 depend obviously on the correctness or otherwise of the determination of the age of the individual deposits in which their remains occur, a matter concerning which the author himself appears frequently to be doubtful, and on whether all the fossil contents of a given bed truly belong thereto, as the author seems always to assume, or may in some cases be mixed with others derived from older horizons. In any case this memoir will prove most useful to all interested in the subject, whether from the geological or palæontological point of view.

VIRUS DISEASES OF PLANTS.—The brief report in *Phytopathology*, vol. 13, No. 4, of the symposium upon mosaic diseases by the Physiological Section of the Botanical Society of America and the American Phytopathological Society records proceedings which

should be of outstanding interest to students of plant pathology and ultimately perhaps of very great importance to agriculture. As a result of the papers communicated at this meeting, it appears that several cases of leaf mosaic and even that important economic disease problem, the leaf roll of potato, may have to be removed from the category of virus diseases and assigned to the category of diseases of which the causal agents are protozoa. Ray Nelson is reported to have produced photomicrographs illustrating definite flagellate protozoa found constantly associated with leaf roll of potato and the mosaic of bean, clover, and tomato. In the light of this paper, the tendency seems to be to regard the intracellular bodies reported by L. O. Kunkel, and by H. H. McKinney, Sophia H. Eckerson, and R. W. Webb, in cases of mosaic disease, as also protozoal in nature. It will be remembered that Kenneth H. Smith briefly reported in NATURE of November 18, 1922, p. 668, the presence of curious intracellular bodies in the case of mosaic of potato, and demonstrated these at the meeting of the Association of Economic Biologists devoted to a discussion of virus diseases. A joint discussion upon this subject between the Sections of Botany and Agriculture is put down for the Liverpool meeting of the British Association, and it is much to be hoped that upon this occasion something may be heard of this new work upon the subject, as the report in *Phytopathology* concludes with the statement that "without doubt this symposium marks an important milestone in the progress of plant pathology."

JAPANESE UROMYCES.—Seïya Ito, professor of phytopathology, College of Agriculture, Hokkaido Imperial University, has contributed a monograph on the Uromyces of Japan, which forms Pt. 4, vol. xi., of the Journal of the College. He describes fifty-six species of Uromyces and three of Pileolaria, giving figures of the spores; 19 species are endemic, 23 common to Europe, and 23 to America. One new species is described, *Uromyces Viciæ-unijugæ* Ito. Eight of these species had not previously been recorded from Japan. Japanese rust fungi will in future be known to us mainly through the investigations of Japanese mycologists, and yet it was only in 1858 that M. J. Berkeley and M. A. Curtis described the first two rust fungi recorded from Japan.

SIZE AND FORM IN THE VASCULAR TRACTS OF PRIMITIVE PLANTS.—Continuing his studies of the influence of size upon form, Prof. F. O. Bower, in the Proceedings of the Royal Society of Edinburgh, vol. 43, Part 1, concludes, mainly as the result of a reconsideration of the figures of the axial stele and petiolar trace in the fossil Cœnopterideæ, that increase in size is followed by decentralisation of the vascular tracts. Various factors, such as mechanical necessities, requirements of tissue ventilation, and so on, may co-operate in bringing about this result, but the author concludes that "there is certainly some other factor which it is more difficult to define than it is to point out its consequences." In the light of the considerations now advanced Prof. Bower is prepared to see a "writing down" of the value of primary vascular characters for the purposes of comparison and phylesis, as such characters may result from homoplastic change consequent upon change in size. The same consideration raises the query whether simplicity of structure is to be associated with small dimensions, so that fossils of small size, like the Rhynie plants, may be anticipated to be primitive.

ABNORMAL WEATHER IN THE BRITISH ISLES.—Exceptional weather conditions in England, either abnormally cold or warm, are of sufficient interest to warrant scientific inquiry, especially with the view ultimately of forecasting such extreme weather changes. The *Meteorological Magazine* for June contains an article by Mr. C. E. P. Brooks of the Meteorological Office on "Sea Temperature, Pressure Distribution, and Weather of May 1923." It is clearly shown that the abnormally cold and showery weather of May was due to persistent north-westerly winds associated with a steep pressure gradient between an anticyclone over the North Atlantic and a depression over the south of Norway. The author attributes the abnormal conditions to the consequences of the abnormal summer of 1921. That summer, which will be remembered as abnormally fine and dry over England, was marked by open stormy conditions in the Arctic Ocean, which set free large quantities of polar ice. This reached Iceland in the spring of 1922, and lowered the temperature of the surrounding ocean; in consequence the pressure rose and the tracks of depressions were driven southward, causing the unfavourable British summer of 1922. Towards the close of 1922 the bulk of the ice passed into the Labrador current, and this helped to lower the temperature of the Gulf Stream. The combined conditions caused an abnormally cold spring this year in the United States. The mean sea temperature immediately to the westward of the British Isles was about 2°·5 F. below the normal, and this low temperature is said to have been partially the cause of the high pressure over the central Atlantic during May. It is to be hoped that the abnormally hot weather of July, with its associated thunderstorms, will be subjected to a similar searching inquiry.

OIL AND GAS RESOURCES, OSAGE, OKLAHOMA.—In Bulletin 686 of the United States Geological Survey is incorporated in one volume the several advance chapters issued between 1918 and 1920 dealing with this important oil-bearing territory in Oklahoma. Apart from the excellent structure-maps included with the geological text, Mr. David White, chief geologist, contributes a significant introduction. The work done on this Osage Reservation is a direct response to what Mr. White rightly terms "the imperative need for increasing to the utmost the petroleum supply of the United States." The area demanded special attention in this connexion for six reasons: it contains a great acreage of unleased oil-lands, the productivity of certain developed areas is already high, the structures are favourable, the oil is of high quality, transport and refinery facilities are already at hand, and the Office of Indian Affairs (which administers lands held in common by the Osage Indians) has been offering leases to competitive bidders. Unfortunately many of these leases, including some already taken up, are, geologically speaking, unfavourable, while others which have been neglected have great possibilities. In these circumstances organised geological survey was essential, and by means of a system whereby reports were published as soon as delivered by the geologists, prospectors and others interested were able to get first-hand information to guide them in their choice of land. The lucid description of structural principles and geological terms employed, together with the explanatory remarks in the introduction, renders this bulletin much less formal in character than is usually the case with technical productions, though a short comprehensive summary of the principal geological and economic features of the whole region might have been included with advantage for the benefit of those unconversant with local detail.

The Liverpool Meeting of the British Association.

I.—LOCAL ARRANGEMENTS.

THE preliminary programme and invitation circular for the meeting at Liverpool of the British Association in September has recently been issued, and the subjects of the various presidential addresses and the chief sectional discussions have been mentioned in NATURE for June 16, p. 825. A short account of the local arrangements may, however, be of interest to members of the Association who intend coming to Liverpool, as well as to others who are as yet undecided about their attendance at the meeting.

The Reception Room and the General Offices will be at St. George's Hall, though accommodation will also be provided at the University for meeting rooms, etc., for offices and members if required. St. George's Hall, though rather more than half a mile from the University, where very many of the sections will hold their meetings, is admirably situated in the centre of the city, close to the railway stations and easily accessible by tram from all parts. The experience of the last meeting showed how excellent a reception room it proved, while its beautiful tessellated floor adds a decorative value most reception rooms lack.

Section E (Geography), and Section F (Economics) will meet in St. George's Hall, the former in the concert room and the latter in one of the large rooms used ordinarily for purposes of the assizes. These rooms being in the same building as the Reception Room itself could not be more convenient. Section H (Anthropology) will meet in the lecture theatre belonging to the Public Museum, not more than a few minutes' walk from the Reception Room. The other sections will all meet in the University buildings. For convenience of getting to and fro between the Reception Room and the University, it is proposed to run a service of motor buses.

The inaugural meeting and presidential address, as well as the evening lecture by Prof. Elliot Smith, will be held in the Philharmonic Hall, which has a seating capacity of about 3000. Citizens' lectures will be given in the Picton Hall, Liverpool, as well as in several of the neighbouring boroughs, and it is also intended to give a few lectures to young people, as these proved such a great success at last year's meeting at Hull.

The Lord Mayor is giving a reception to members of the Association in the Walker Art Gallery and Museum and Library (all three buildings being "en suite") on Thursday evening, September 13, and for that occasion it has been arranged to exhibit the greater portion of the permanent art collections of the city as well as to show exhibits of interest in the Library and Museum.

On the last evening of the meeting, Tuesday September 18, a scientific soirée will be held at the University. This gathering, based on the lines of the Royal Society functions, will, it is believed, be of the greatest interest, as a very large number of exhibits and experiments illustrating recent developments in science will be on view. There will also be a series of lecturettes by eminent men of science. It may be mentioned that the committee engaged in the organisation of this soirée at the University hope that as many members of the Association as possible will wear full academic dress on that occasion.

During the whole of the meeting, an exhibition of scientific apparatus, specimens, diagrams, etc., representative of the work of all the thirteen sections of the Association, will be on view in the Central Technical School, kindly placed at the disposal of the local committee by the Technical and Commercial Education Sub-Committee of the Corporation. This exhibition should prove of interest to all members, if one may judge from the small sectional exhibits which have been features of the Association meetings on several occasions during the last decade. All members of the Association will be admitted free.

A comprehensive series of excursions and visits to works and places of interest in the neighbourhood is being arranged, and the local committee hope the programme will provide interest for all.

A special handbook is in preparation. It will contain a number of articles dealing with the whole district of which Liverpool is the centre, rather than being restricted to the city and its immediate environs. It is hoped members will find it of more than merely ephemeral interest, as the articles are all by authors well qualified to write on their particular subjects.

Every effort is being made by the local committee to make the meeting a signal success. It is hoped very much that all those interested in science, even if not actually professional scientific workers, will attend. The local programme is developing week by week, and there is no doubt that by the date the meeting commences, provision will have been made for every minute of the member's day. ALFRED HOLT.

The Thunderstorm of July 9–10 over Southern England.

THE thunderstorm which visited London during the night of July 9–10 will find a place on the list of famous storms rather for its duration and for the spectacular effect produced at night by the incessant lightning, than for the quantity of rain associated with it or the damage done, though neither of these was by any means negligible. It is too early yet to attempt anything like a complete account of the storm, but data already at hand, and personal observations generously placed at my disposal, render a preliminary note possible.

Apart from the long duration, the most noteworthy general characteristics appear to have been the sudden development with little in the way of sky signs to aid the isolated observer, the general lack of hail, the absence of any marked squalls of wind at the surface, and the very marked preponderance of cloud-to-cloud discharges, without which the damage might have been very much worse.

The storm[1] first made its appearance about 8.30 P.M. (Greenwich time) on the south coast, where it was seen approaching from the south-east. It then progressed N.N.W., in the direction of London, where a corresponding phase was reached about two hours later, the system having advanced at a speed of roughly 25 miles per hour. This rate of movement appears to have been maintained in the same direction across Bedford and Peterborough, and then, rather faster, on to Hull and Middlesbrough. Thunderstorms which occurred later on July 10 at Berwick,

[1] The disturbance as a whole is referred to as the storm, but the system undoubtedly had several nuclei.

Aberdeen and in the Shetlands, all on the continuation of this line, were not improbably related to the same general cause, though the continuity of the advance of the original system cannot be verified.

The main rainfall was confined to a belt between 30 and 40 miles in width, lying along the track of the storm. In this zone, falls were probably everywhere greater than 1 in., at least as far north as the Wash, while they equalled 2 in. in many places, and reached 3 in. in isolated patches. On the south coast this belt of heavy rain extended from a point between Worthing and Brighton to a point between Eastbourne and Hastings, while central London lay in the middle of the affected zone. Outside this band, amounts fell off quickly, particularly on the eastern side, where the boundary was sharply defined; for example, while Eastbourne received 1¾ in., Hastings and places further east escaped rain, and while Tunbridge Wells experienced nearly an inch, there was none at Maidstone.

Over the southern portion of the track, including London, rain fell practically continuously for more than 6 hours, so that, allowing the speed of 25 miles per hour, the main travelling rain system responsible for this belt of precipitation was here probably about 150 miles long in the direction of its motion, and 35 miles broad.

In the north, the amounts and duration of rainfall appear to have been rather less than in the south of England.

Striking agreement in time is shown by the hyetograph and microbarograph records at South Kensington between sudden changes of pressure and intense bursts of rain, particularly just after 2 A.M. (G.M.T.). There is also agreement between the sudden changes of pressure at South Kensington and those recorded at Kingsway, London, W.C.2, by the Dines float barograph, which shows the absolute magnitude of the pressure changes. It is interesting to mention that an observer in Hampstead noted quite independently that the worst crashes, followed immediately by torrential rain, occurred at 2.15 A.M. and 3.45 A.M. (G.M.T.). The first of these was about 10 minutes after the occurrence of the very pronounced peak in the Kensington microbarograph record and corresponding heavy rain shown by the hyetograph record. Thus, allowing 4 miles between the places of observation, we again find phenomena associated with the storm travelling at about 25 miles per hour.

Although a closer investigation is desirable before putting forward an explanation of the storm with full confidence, an examination of the weather charts and upper air data available brings to light some very suggestive facts. Measurements of upper winds on the evening before the storm show that between about 6000 feet and 18,000 feet above the surface there was a general wind current over the affected area agreeing very closely indeed in direction and speed with those of the movement of disturbance itself, and observations of the drift of cirrus cloud show that above this the air motion was probably from about S.W. Now the weather charts for July 8 and 9 show an anticyclone over the Continent and a depression almost stationary off the West of Ireland, and, further, a current of air of undoubtedly polar origin, and therefore probably having a low upper-air temperature, circulating round the latter.

It seems very likely that some of this polar air, in arriving, at some upper level, over the south-west districts of England and endeavouring to work its way northwards, side by side with the very warm air of continental origin over the eastern districts, spread laterally over the latter, producing the travelling area of instability necessary to explain the phenomena described above.

M. A. GIBLETT.

The Pascal Commemoration on the Puy de Dôme.

THE tercentenary of the birth of Blaise Pascal (born June 19, 1623, died August 19, 1662) was celebrated at Clermont-Ferrand in a series of fêtes at which the President of the French Republic, M. Millerand, and the most distinguished French scholars and philosophers met to do homage to his great genius.

The culminating interest of the celebrations was the visit to the summit of the Puy de Dôme on Sunday, July 8, to commemorate the experiment devised by Pascal and carried out successfully by his brother-in-law Florin Périer, an experiment as famous in its day and as decisive in its significance as the eclipse expedition of May 1919 has proved to be in our day. In demonstrating that the atmosphere has weight it destroyed a principle of the old physics which had become authoritative, the principle that Nature abhors a vacuum, and at the same time it inaugurated a new scientific concept in physics. The rain poured as we gathered on the summit where, above the ruins of an ancient temple of Mercury, a modern meteorological observatory has been erected. Those who were so fortunate as to find room in the small cupola of the observatory, however, are not likely to forget M. Painlevé's discourse. Round the President were grouped the Prefects of the Departments, the Mayor of Clermont, the Rector of the University, Senators and Deputies, the representatives of the Institut de France, and the foreign guests of the Municipality. In an eloquent oration M. Painlevé described the inception of the great experiment and discussed its significance.

No one of that large company (the Municipality entertained three hundred guests at the *déjeuner* on the mountain) who had ascended the mountain by the modern means of electric traction with luxurious comfort in little more than an hour can have failed to reflect on the different conditions which prevailed in Pascal's time, and on the enormous difficulties of the original expedition. Those who are interested may read the full and careful report of it in Périer's letter to Pascal. It was arranged that first of all two sets of apparatus should be tested side by side to see that they gave identical measurements, that is, to see that each column of mercury in the inverted tubes (barometer tubes) remained at the same height. One set was then carried up to the top of the mountain and the other left behind in the church of the Minimes at Clermont. The experiments with each set were made at the prearranged hour and precisely recorded. The significance of the experiment was its uniqueness. It differed entirely from observations which any one might make with the scientific intention of recording facts; it differed entirely, for example, from observations such as those of Tycho Brahe. It was uniquely designed to test a physical theory which would stand or fall by the result. It had been known practically by engineers for a long time that there was a natural limit to the action of a pump, and in the crucial experiment of Torricelli with the column of mercury in the glass tube closed at one end and immersed in liquid at the other it was shown that the principle was

the same as that which was applied to the action of pumps, with the difference presumably due to the density of the liquid.

The problem was not the fact but its significance. The Aristotelians held that it had been definitely established that the atmosphere had no weight, and what is quite certain is that no means of discovering its weight, if it had any, then existed. It is therefore strikingly analogous to the case of the hypothetical ether when physicists were engaged in devising means of revealing its presence. Descartes, though entirely opposed to the Aristotelians, yet held on *a priori* grounds that the universe was a plenum. He needed the concept in order to explain the vortex motion which in his view accounted for the variety of material forms. The apparent vacuum in the Torricelli tube he supposed to be due not to an absence but to the presence, or rather to the entrance under the conditions of the experiment, of a very subtle matter. Pascal, on the other hand, to quote M. Painlevé, " s'inspirant de Galilée et Torricelli, entre la science d'Archimède et la science moderne, jette un pont par-dessus vingt siècles. La presse hydraulique, le baromètre observé à diverses altitudes, ce sont les illustrations d'une statique nouvelle qui embrasse à la fois, dans les mêmes principes, l'équilibre des liquides et celui des gaz." Let us imagine, he went on to say, that through some disaster everything which we now know about Pascal had been lost to us save only his scientific writings. In what light would he appear to us? We should be right to point him out as the first of the positivists methodically disengaging facts from the confusion of words, discrediting purely verbal definitions, " cet air subtil qui aurait des inclinations," " cette lumière qui est un mouvement luminaire de corpuscules lumineux."

Other memorable discourses followed, in particular one by M. Picard, before we sat down to the sumptuous banquet which the Municipality offered its guests. When this was concluded the President of the Republic rose and to the enthusiastic applause of the company, though, it must be admitted, to the general surprise of those who were thinking of Pascal, delivered an impassioned and truly eloquent speech on the politics of the hour, which was immediately transmitted round the world. The rain ceased, and we made the return journey to Clermont favoured by a clear sky and splendid view over the grand Auvergne country. The city was gaily decorated for another celebration in the square over which the statue of the seated Pascal presides. H. WILDON CARR.

An Advance in Photometry.

HERR E. STEINKE, in an investigation into the accuracy of the Wien-Planck law in the ultra-violet region of the spectrum, has recently made use of Elster and Geitel's potassium photo-electric cell, as neither the thermopile nor the bolometer was sufficiently sensitive to measure the minute quantities of radiant energy involved (*Zeits. f. Physik.*, 11. 4 and 5, pp. 215-238, 1922).

Herr Steinke has found it possible to increase the sensitiveness of the cell enormously, by increasing the voltage between the potassium anode and the platinum cathode; and has carefully investigated the behaviour of the cell under these conditions. For red light, $\lambda = 630\mu\mu$, an increase in voltage from 20 to 210 multiplies the sensitiveness by 1045 and for violet light, $\lambda = 462\mu\mu$, by 1595. This is due to the increased ionisation from collisions between the greatly accelerated electrons and the argon contained in the cell.

It was not possible to apply such a high voltage to the cell suddenly without a luminous discharge; it was necessary to raise it gradually for hours or even days at a time, and it was then possible to reach the 210 volts already mentioned. At 212 volts luminous discharge took place, after which the cell discharged at 162 volts, recovering if left to itself for some days, so that the potential could again be raised to 200 volts. In forming the cell, as above, for high voltages it was found that each time the voltage was increased there was a strong " darkness " current at first; which diminished in the course of time to zero for lower voltages, and at 210 volts to a moderate value after several days.

When the cell is prepared in this way, and is illuminated, a fatigue effect is observed, the time required for the thread of the Lutz-Edelmann electrometer to move from a certain division on the scale to another (85 to 65) gradually increasing to a limiting value, which in one experiment was reached in about fifteen minutes. This limiting value was determined in all the experiments. These were always made in the order of increasing illumination, as it was found that a high illumination produced a kind of after action, and a small illumination measured shortly afterwards showed a higher value than the real one. For the high voltages employed the limiting value of the photo-electric current was not proportional to the illumination, as it was found to be by Elster and Geitel for moderate voltages; but the following relation was proved to exist, $I^z = ML$; where I is the photo-electric current, L the flow of radiant energy, and z and M are constants. The cell constant z varies with the wave-length, and with the voltage applied to the cell; for small voltages it scarcely differs from unity, and the law becomes identical with that of Elster and Geitel; for $\lambda = 316\mu\mu$ z was observed to be 1·3495, with 208 volts on the cell terminals, and intermediate values were found for other wave-lengths and voltages.

Using the method described, Herr Steinke has measured the exponent c_2 in Planck's formula $E\lambda = \frac{C}{\lambda^5}\frac{1}{e^{c_2/\lambda T} - 1}$ for a number of different wave-lengths, including $340\mu\mu$ and $316\mu\mu$ in the ultra violet. The mean value is 14,385, the largest variation from this being 0·63 per cent., and the mean probable error 0·16 per cent. The actual probable error is rather greater than this, owing to the difficulty of determining the wave-length of the rays employed, which were separated from the light of a carbon incandescent lamp by filters. The value agrees satisfactorily with that determined by previous observers for visible radiations. The observations also show that carbon radiates, throughout the range of wave-lengths investigated, as a grey body. Herr Steinke proposes to continue the investigation, and to measure the constant C in the above formula.

It would appear that the improved method of using the photo-electric cell should prove of the highest value in work on the spectrum, particularly in the ultra violet.

International Conference on Nature Reserves.

THREE Associations in France entitled, respectively, the Société Nationale d'Acclimatation de France, the Ligue Français pour la Protection des Animaux, and the Société pour la Protection des Paysages de France, recently invited the Royal Society for the Promotion of Nature Reserves to send delegates to attend a conference " Pour la Protection de la

Nature." This Conference was held in Paris on May 31-June 2 last, and at the request of the Society for the Promotion of Nature Reserves it was attended by Lord Ullswater, Mr. E. G. B. Meade Waldo, and Mr. Percy R. Lowe (British Museum, Natural History).

The Conference was presided over by M. Mangin, director of the National Museum of Natural History in Paris, and was divided into five sections: (i.) fauna, (ii.) flora, (iii.) geological, (iv.) sites and landscapes, (v.) general.

At the sittings of the various sections papers were read in French by many members upon a great variety of topics. Most of the speakers dealt with the subject matter of the Conference so far as it affected their own country or their own special part of it, and few treated the subject from a general point of view. The paper read by the Swiss delegate was a striking exception to this rule, while M. Burdet's lecture, illustrated with slides, which dealt with the Nature reserves of Holland, was a very useful and practical contribution to the Conference.

It was felt by the representatives of the Royal Society for the Promotion of Nature Reserves that in any similar future conference a series of resolutions, not too many in number, should be prepared and circulated some weeks before the Conference, so that there might be ample opportunity for their discussion, emendation, adoption, or rejection. Such resolutions should deal with the subject matter from a general point of view, and should indicate the best method of establishing Nature reserves, whether by State legislation or private enterprise; in what manner such reserves might be best administered; how funds might be obtained for the purpose; how the rights of individuals in the lands in question are to be protected, modified, or abolished; how the selection of the proposed public parks or nature reserves is to be determined; and in what manner subordinate questions arising therefrom are to be answered.

University and Educational Intelligence.

GLASGOW.—Prof. Andrew Gray has intimated his desire to retire from the chair of natural philosophy on September 30 next, on grounds of health. Prof. Gray has occupied the chair since 1899, when he succeeded Lord Kelvin. During his tenure of office the fine institute of Natural Philosophy, which was designed and erected under his direction, has been added to the numerous new scientific buildings of the University. Some 1100 students a year are accommodated in its spacious laboratories and classrooms.

CAMBRIDGE.—In connexion with the recent international conference of chemists in Cambridge honorary doctorates in science were conferred upon a number of distinguished foreign chemists. In introducing them to the University the Public Orator spoke as follows:

Multa nobis antiquitas tradidit quibus adhuc nititur humana vita; multa recentiores reppererunt et quotidie nova profert usus. Quantas omnium mutationes induxerit vapor domitus et quasi freno subditus, quantas explorata res chemica, nulli non est notum. Inter se ergo consociati sunt illi qui, sive ipso veritatis amore, sive commercii causa promovendi chemica tractant, et quotannis concilium convocant. Hoc anno patriam nostram petierunt et inter urbes Britannicas Cantabrigiam. Multarum gentium legatos praesentes videre laetamur; abesse adhuc dolemus nonnullarum. Universitas nostra voluit e tanta frequentia quosdam titulo doctoris decorare, quo patefactum sit omnibus quanto honore et haec studia et qui eis se dederint universos habeamus.

Primum vobis praesento ALBINUM HALLER. Quidquid enim in scientiis apud Francos agitur, in Academiam suam Scientiarum conferunt; hoc in circulo conveniunt omnes qui haec studia prosequuntur; huic quasi senatui curiaeque quotannis praeficitur vir egregius. Quem ergo fraternitas sua honore tali dignata sit, illum et nos honorare volumus.

Sequitur WILDER DWIGHT BANCROFT et studiis et affinitate nobis conjunctus, qui alter Ulixes multorum providus, novam Ithacam novis artibus illuminavit.

Itidem provenit ERNESTUS JULIUS COHEN, quem in Academia sua Rheno-Trajectina, ut Ovidium alterum

> in nova fert animus mutatas dicere formas
> corpora.

Francus et alius insequitur, apud Parisios in Collegio Francorum professor, CAROLUS MOUREU, non ille rerum contemptor minutissimarum sed inquisitor acerrimus.

Hodie, dum procul horrificis tonat Aetna ruinis, non usitato salutamus Italum, RAFAELEM NASINI, quem nobis misit urbs Etrusca, Vergilio nota, Alphaeae ab origine Pisae. Hic explorandos sibi Volcani delegit vapores,

> qualis sese halitus atris
> faucibus effundens supera ad convexa volarit,

necnon et Albunea qualem

> exhalet opaca mephitim.

Helvetius quoque adest, iam senior, Universitatis Genevensis professor, AMATUS PICTET, qui bases rerum inspexit, ad investigandum curiosus quae vacuum per inane fieri possint.

Gandavensis item Academiae professor advenit, cuius si velitis opera recognoscere sunt qui possint oratione fluentiore vobis exponere; constat tamen illorum qui talia tractant nullum FREDERICO SWARTS antecellere.

> Felix qui potuit rerum cognoscere causas!

Credo equidem, sed non omnibus omnia concessere Parcae. Arcadiam nactus sum, Musarum antiquiorum aedituus indignus, contempto in fano ministrare laetus. Vos quorum est prodigia tractare e terra Cham exorta, quaeso mihi ignoscite, si linguarum nescius singularum Latine vos gaudere iubeam universos.

LIVERPOOL.—Following on the death of his widow, the estate of the late Prof. Campbell Brown has been handed over to the university under the conditions stated in his will. These provide that: (1) A Campbell Brown chair of industrial chemistry shall be established with an endowment of 1200*l*., the first professor to specialise in oils, fats, and waxes. In the first instance the salary shall be 1000*l*. per annum. (2) The income of a sum of 5000*l*. shall be placed at the disposal of the professor for the upkeep of his department. (3) A Campbell Brown fellowship, value 150*l*. per annum, for senior and honours chemistry students, not necessarily trained in Liverpool, shall be established; and (4) The balance of the bequest shall be invested and accumulated until sufficient income accrues to enable entrance scholarships of the value of 80*l*. per annum, tenable for three or four years, to be offered.

LONDON.—The following doctorates have been awarded: *Ph.D.* (*Science*): Mr. L. Hall (Battersea Polytechnic) for a thesis entitled "The Study of

Optical Activity"; Mr. H. Phillips (Battersea Polytechnic) for a thesis entitled "The Relation between Chemical Constitution and Optical Rotatory Power"; Mr. A. Brammall (Imperial College, Royal College of Science) for a thesis entitled "The Mineralogy, Structure, and Petrology of the Dartmoor Granite"; Mr. H. Schofield (Imperial College, Royal College of Science) for a thesis entitled "The Measurement of Thermal and Combustion Efficiency of High Speed Multi-Cylinder Internal Combustion Engines by the use of a new Optical Indicator," and Mr. R. L. Smith-Rose (Imperial College, Royal College of Science and City and Guilds College) for a thesis entitled "On the Variations of the Apparent Bearings of Fixed Radio-Transmitting Stations." *Ph.D.* (*Engineering*): Mr. H. F. G. Letson (East London College) for a thesis entitled "The Experimental Determination of the Temperature Distribution, and Calculation of the Thermal Stresses in a Diesel Engine Cylinder Liner."

Applications are invited for the William Julius Mickle fellowship, of the value of at least 200*l.*, awarded annually to the man or woman resident in London and a graduate of the university who is deemed by the Senate to have done most to advance medical art or science within the five preceding years. Applications must reach the Principal Officer of the University, South Kensington, S.W.7, by at latest, the first post of October 1 next.

ON July 27, the summer meeting of the University of Oxford Delegacy for the Extension of Teaching opens with an inaugural lecture by Sir Michael Sadler. We have already referred to the excellent programme which is being provided this year (NATURE, May 19, p. 688), which includes lectures on the functions of universities, the economics of English country life, and research in organic chemistry. Special railway facilities are being offered for those desirous of attending the meeting. Full particulars can be obtained from the Secretary, University Extension Delegacy, Examination Schools, Oxford.

THE jubilee celebrations of the Cambridge University Local Lectures began on Friday, July 6, with a special Congregation for the conferment of honorary degrees for distinguished service in the cause of university extension, namely, the degree of LL.D. on Sir Michael Sadler, Mr. R. G. Moulton of Christ's College, and Mr. Albert Mansbridge, and the degree of M.A. on Mr. G. P. Bailey, Mr. J. H. Fisher, and Mr. Alfred Cobham. On the Saturday and Monday there were meetings of a conference on extra-mural teaching. Speeches at the conference emphasised the far-reaching effects of the movement initiated in Cambridge by James Stuart in 1873, which has spread not only throughout the British Empire but to most of the civilised countries of the world, attaining its greatest and most various developments in the United States. The speeches dwelt also on the value to extra-mural lecturers of the stimulation they receive from lecturing to (and being cross-examined by) adult audiences, contrasting their eagerness with, and perhaps exaggerating, the lethargy and "anxiety to curb an exhibition of enthusiasm" of the normal undergraduate student. In the opinion of the Master of Balliol, those who are responsible for the further development of the movement are at a parting of the ways, and careful guidance will be needed if it is not to suffer the usual penalty of success and become absorbed in its own mechanism. Progress will depend largely on co-operation between universities, local authorities, and voluntary bodies.

Societies and Academies.

LONDON.

Mineralogical Society, June 19.—Dr. A. Hutchinson, president, in the chair.—L. J. **Spencer**, with chemical analyses by E. D. **Mountain**: New copper-lead minerals from the Mendip Hills (Somerset). Mendipite ($2PbO . PbCl_2$), which occurs as crystalline nodules in manganese-ore, is recorded from new localities. Chloroxiphite ($2PbO . Pb(OH)_2 . CuCl_2$) as green monoclinic blades resembling epidote, and diaboleite ($2Pb(OH)_2 . CuCl_2$) as bright-blue tetragonal plates resembling boleite, both occur embedded in the mendipite. Hydrocerussite ($2PbCO_3 . Pb(OH)_2$) is abundant, sometimes as large crystals (*i.e.* crystallised "white lead"). Crednerite ($CuO . Mn_2O_3$) forms fan-like aggregates of thin plates. Pyromorphite was, some centuries ago, evidently an important ore of lead in the Mendips. Wulfenite and mimetite have been found at Higher Pitts near Priddy. The various minerals show progressive stages of alteration with some well-marked pseudomorphs: mendipite ⟶ hydrocerussite ⟶ cerussite; chloroxiphite ⟶ hydrocerussite + malachite I ⟶ cerussite + crednerite ⟶ malachite II.—W. F. P. **McLintock**: On a petalite-bearing rock from Devonshire. The well-known aplite from Meldon in Devonshire develops in certain parts of the intrusion a soda-lithia phase rich in the rare lithium-aluminium silicate, petalite. This mineral, not previously known from Britain, occurs as one of the final products of consolidation of the aplite either in coarse-grained veins of pegmatite associated with quartz, orthoclase, albite, a lithia-bearing mica, tourmaline, and apatite, or as irregularly shaped masses throughout the rock itself. The petalite gives rise by decomposition to the pink clay, montmorillonite, so well known from this locality. Certain other veins, free from petalite, are also present, the most interesting constituents of the rarer types being prehnite, axinite, and a pleochroic cordierite. The apatite in the aplite is a pneumatolytic mineral occurring not only in the rock as ophitic patches enclosing quartz and felspar, but also impregnating certain xenoliths of peculiar type.—A. **Brammall** and H. F. **Harwood**: The accessory minerals of the Dartmoor granite. Tourmaline, which is one of the minerals identified, originated at two stages in the cooling history of the intrusion: (1) pre-solidification—primary and secondary; (2) post-solidification—secondary. The more severe and widespread pneumatolysis and the lodes are referred to a post-solidification stage.—Seitarō **Tsuboi**: (1) Optical dispersion of three intermediate plagioclases. The principal refractive indices, α, β, γ, of (*a*) oligoclase from Hawke mine, Bakersville, North Carolina, (*b*) andesine from Maeyama, Shinano, Japan, and (*c*) labradorite from County Down, Ireland, for light of 9 different wave-lengths, and the optical orientations of the first and the third of these felspars, for light of 5 different wave-lengths (700, 644, 589·3, 535, 508·5$\mu\mu$) were determined. (2) A dispersion method of determining plagioclases in cleavage-flakes. The method is based on the principle of H. E. Merwin's improved immersion method. By means of a diagram a quick and exact determination of plagioclases is possible. It is applicable to small crystals such as are common in rocks.—C. S. **Garnett**: The "toadstone-clays" of Derbyshire. The olivine-dolerites ("toadstones") of Derbyshire undergo two types of alteration: (1) by ordinary weathering to limonite or ochreous deposits; (2) in the absence of oxidising agents under a limestone covering, they may pass through dolerite-greenstone and "green-earth" to a greenish-white

or almost white clay ("toadstone-clay") with the composition $2Al_2O_3 . 6SiO_2 . 3H_2O$. — G. T. **Prior**: (1) The meteoric stone which was seen to fall at Ashdon, near Saffron Walden, Essex, on March 9, 1923. The stone, which weighed about 1300 grams, is a white chondrite showing on one face well-marked radiating lines of flow of the fused crust. (2) The Sinai meteorite. The meteoric stone of 1455 grams which was seen to fall near Kantara in the north of the Sinai Peninsula in July 1916 is an intermediate hypersthene-chondrite, having a percentage of nickel-iferous iron of about 8·6 in which the nickel amounts to about 15 per cent.—G. **Greenwood**: Communications from the Crystallographic Laboratory of the University of Manchester. No. 1. The detection of rotatory polarisation in an orthorhombic crystal exhibiting crossed axial dispersion. A plate perpendicular to the acute bisectrix of a crystal of triphenyl-bismuthine dichloride when in the extinction position transmits a brilliant green monochromatic light due to circular polarisation.—A. F. **Hallimond**: The chemical classification of the mica group. I. The acid micas.

Linnean Society, June 21.—Dr. A. B. Rendle, president, in the chair.—E. **Heron-Allen** and A. **Earland**: The Foraminifera of Lord Howe Island, South Pacific. Some 199 species of Foraminifera, identified from material collected by Prof. R. Douglas Laurie at Lord Howe Island in 1914, and including two new genera and seven new species, were described. The chief feature of the collection is the prevalence of forms in the condition of reproduction, (*a*) by viviparity, and (*b*) by budding.—T. A. **Dymes**: Seeds of the marsh orchids. The marsh orchids fall into two groups: (1) Maculatæ, and (2) Latifoliæ. The seeds of Maculatæ differ from those of the Latifoliæ in that the testal cells are sculptured. Seeds even from the same plant may vary greatly, though *Orchis majalis*, Reich. has uniform seeds. —A. **Dendy** and Miss Leslie M. **Frederick**: On a collection of sponges from the Abrolhos Islands, Western Australia. There are forty-eight determinable species, of which twelve are regarded as new. The Calcarea identified include a number of fine specimens of the rare *Grantiopsis cylindrica*, and there is a new species of the rare and remarkable "Pharetronid" genus Lelapia, and a new genus of Leucascidæ. The Tetraxonida form the bulk of the collection. The sponge fauna of the Abrolhos Islands is mainly intermediate in character between that of the more westerly Indian Ocean and that of the more easterly Australian coasts; but it contains a small element apparently derived from the north.—Ethel N. Miles **Thomas**: Observations on the seedling anatomy of the genus Ricinus. The presence of *alternate* or *root* xylem in the hypocotyl and cotyledons of several species of Ricinus, including *R. communis*, is established. At an early stage the alternate or radial elements *alone* are lignified. The tissue groupings associated with root structure are only found low in the axis, while above the collet eight stem bundles are found which are continued upwards as the four equally spaced bundles of the cotyledons. In addition, there are alternate xylem elements in the cotyledonary plane, *i.e.* that passing through the centre of each cotyledon. The existence, as well as the resorption, of these elements, which are usually in direct continuity with the cotyledonary root poles, has now been established in a large number of dicotyledonary species.—C. H. **O'Donoghue**: Opisthobranchiata collected in the Abrolhos Islands.

Royal Anthropological Institute, June 26.—Mr. H. J. E. Peake in the chair.—Hazzledine **Warren**: The palæolithic succession of Stoke Newington. The latest group which is found upon the Stoke Newington "floor" is a clearly-defined Mousterian industry, with fine examples of both *racloirs* and of the equally characteristic trimmed-flake points. Delicately finished pointed and ovate implements are also found. This "floor" occurs in the upper sandy beds of the terrace deposits, associated with a temperate flora, *Corbicula fluminalis*, and the northern migrating animals. The series of intermediate age are found in the underlying gravels of the terrace, and they constitute an equally well-defined late Chellean group. They are contemporary with the gravel. The third and apparently oldest series are greatly abraded derivatives, and they frequently exhibit a second series of abrasions and chips that are later than the patination of the flint. The dominant form of implement is a rude, thick, ovate type, made with a minimum of flaking, although occasionally better-finished examples are found. The pointed form occurs, but is less common. This series is comparable with the "Hill group" described by Prestwich from the Kentish plateau, and is considered by some to be of Early Acheulean date. There is, however, much cumulative evidence from other localities, besides Stoke Newington, which would appear to suggest that the derivative series of Stoke Newington may be older than the Chellean group as defined by Commont from the Somme Valley.

Aristotelian Society, July 2.—Prof. A. N. Whitehead, president, in the chair.—M. **Ginsberg**: The category of purpose in social science. The interpretation of purposive activity as consisting in the realisation of conscious factors involved in voluntary behaviour is misleading when applied to creative work and practical activity, and it breaks down in the biology of the lower organisms. The purposive must be related to the teleological. A comparison of mechanical, organic and purposive wholes shows the importance of viewing purposive wholes as a species subsumed under a wider genus, conational wholes. These may be defined as systems which maintain themselves as wholes by the striving of their parts towards mutual adjustment. They vary enormously in the degree of integration achieved, and the explicitness with which the ends of the system are realised by the parts of which they consist. Perhaps organisms are conational wholes. There are all sorts of organisms belonging to different levels of integration. So there are all sorts of social wholes, varying in plasticity, articulateness, and comprehensiveness. It is important to recognise integrations of different orders or levels, and the kind of integration achieved by societies is not the same as that which characterises the holding together of mental processes in one stream of consciousness. Institutions and tradition may be regarded as the result of trial-and-error experiments towards mutual adjustment.

DUBLIN.

Royal Dublin Society, June 26.—Prof. J. A. Scott in the chair.—H. G. **Becker**: Improved methods of evaporation under laboratory conditions. A special form of oil bath incorporating a wind-tunnel was used to determine the rate of evaporation of distilled water at different temperatures from 30° C. to 100° C., and in currents of air of different speeds, the rate of evaporation being measured by observing the fall of a glass float in the liquid. The rate is proportional to the vapour pressure up to 90° C.; above this temperature it increases more rapidly. By maintaining the water at 95° C. in a current of air of 500 ft.

per min. a sevenfold increase in the rate of evaporation was obtained as compared with the rate of evaporation on a water or steam bath. A new form of laboratory evaporator described consists of a glass bulb, containing the liquid, mounted on fibre bearings, and rotated by a small motor, while it is heated directly by a bunsen burner. The rotation prevents the liquid in contact with the glass bulb from becoming super-heated, and, besides keeping the liquid mixed, spreads it out in a thin film on the upper surface of the bulb while a current of air or indifferent gas can be blown through the bulb. It is possible to obtain rates of evaporation up to twenty-four times as great as that on the water bath.—H. G. **Becker** and W. E. **Abbott**: A rapid gasometric method of estimating dissolved oxygen and nitrogen in water. The gas is expelled by dissolving an electrolyte in the water, the displaced gas being liberated in a partial vacuum, collected, and measured. Caustic potash is the most satisfactory electrolyte. The analytical results are comparable with those obtained by the Winkler and boiling-out methods. The advantages claimed are simplicity of apparatus, rapidity, and smallness of the water sample required for a determination.—W. R. G. **Atkins** and M. V. **Lebour**: The hydrogen ion concentration of the soil and of natural waters in relation to the distribution of snails. The hydrogen ion concentration of the soil is a factor limiting the distribution of snails, which are far more numerous between $P_H 7$ and $P_H 8$ than elsewhere. Of 27 species of snails found in the districts studied, 4 species occurred at $P_H 5$, 20 species at $P_H 7$, and 14 species at $P_H 8$. Snails with hyaline shells occur over a wide range, but those with calcareous shells are limited to the more alkaline soils. Granite and quartzite regions have few species, basaltic districts have a more numerous fauna, and limestone areas are rich both in variety of species and number of individuals. The distribution of some species within the British Isles is probably explained by the "age and area" theory of Willis, rather than by a limitation through unfavourable ecological factors. *Cochlicella barbara* appears to have a western, and *Theba cantiana* an eastern, origin.

PARIS.

Academy of Sciences, June 25.—M. Albin Haller in the chair.—Maurice **Hamy**: The determination of small diameters by the interference method.—P. A. **Dangeard** and Pierre **Dangeard**: Second note on the vitality of leaves of Aucuba preserved in a vacuum. The Aucuba leaf after being in a vacuum for twelve months resembled, macroscopically and microscopically, a freshly plucked leaf. It retained its original green colour, and the vitality of its cells was undiminished.—Morin **Molliard**: The determining factor in the formation of conidia in *Sterigmatocystis nigra*. The formation of conidia is determined by a deficiency of phosphorus or other nutritive element in the culture fluid, together with an excess of potassium.—V. **Grignard** and R. **Escourrou**: The methylheptenols: their ketonic decomposition.—F. H. van den **Dungen**: Calculation of the simple poles of a meromorphic function.—Gino **Fano**: The congruence of the normals to a quadric.—L. **Décombe**: The analytical theory of irreversibility. Elementary isokinetic transformations.—C. **Gutton**, S. K. **Mitra**, and V. **Ylostalö**: The high-frequency discharge in rarefied gases. The frequency range in these experiments varied between 50 and 2,140,000, and tubes with internal and external electrodes were used, the gas being dry air. The potential varied with the frequency, and for tubes with internal electrodes the difference of potential always increased with the frequency; for tubes with external electrodes the pressure of the gas affected the relation between potential and frequency.—Jacques **Errera**: Colloidal supports for obtaining the emission spectra of solutions. The spark is passed between rods of gelatin containing the salt under examination; the method has the advantage that fewer lines are introduced into the spectra by the electrodes than when metal or glass supports are used for the solutions.—M. **Duffieux**: The mass of the particles which emit the secondary spectrum of hydrogen. The experiments described lead to the conclusion that all the lines examined in the secondary hydrogen spectrum must be attributed to the molecule of hydrogen.—Mlle. St. **Maracineanu**: Researches on the constant of polonium. Published values for the period of polonium vary between somewhat wide limits, 134·5 to 143 days. The value 139·5 days is regarded as the most probable. Deposition of radioactive substances on glass is preferable to deposition on metal plates in researches of this nature.—G. **Dupont** and L. **Desalbres**: A curious case of separation of optical isomerides by distillation and by crystallisation. A partial separation of active and inactive pinene can be made by fractional distillation with a very efficient column; evidence of a similar separation has been obtained by fractional crystallisation at $-75°$ C.—M. **Geloso**: Isotherms of the adsorption of salts by manganese dioxide. Experimental results of the adsorption of copper, nickel, and iron by precipitated manganese dioxide: a simple expression is deduced which accurately expresses the experimental data.—Paul **Pascal**: The magnetic properties of cyanic and cyanuric compounds. From a study of the magnetic susceptibility of compounds containing the groups (CNO) and $(C_3N_3O_3)$ and assuming the law of additivity, conclusions are drawn concerning the constitution of these compounds. Cyanuric acid is regarded as possessing a structure similar to the benzene nucleus, but isocyanurates and cyamelide differ in structure, although containing a six-atom ring.—André **Charriou**: The reciprocal displacement of substances carried down by precipitates. Chromic acid is carried down by a precipitate of aluminium hydroxide, and this cannot be washed out with water or with solutions of salts of monobasic acids; the chromic acid, however, can be removed completely by washing with solutions of salts of dibasic or tribasic acids (sulphate, oxalate, phosphate).—Henry E. **Armstrong**: The origin of osmotic effects. Hydronodynamic transformations in aqueous solutions. Discarding the Arrhenius theory as irrational and in disagreement with the facts, a résumé of the hydrone theory is given, and this is regarded as explaining all the properties of aqueous solutions.—Alfred **Gillet** and Fernand **Giot**: It is common knowledge that treatment of the fibre before dyeing with copper salts in some cases increases the fastness to light. It is shown experimentally that a preliminary treatment of the fibre with cuprous salts exerts a strong protective action against light for the dye 2B diamine blue.—Max and Michel **Polonovski**: The constitution of eserine.—Raymond **Delaby**: The action of formic acid on ethylglycerol. Conversion into β-ethylacrolein. The decomposition of the crude mixture of formins from ethylglycerol gives two unsaturated alcohols, vinylethylcarbinol, $CH_2 : CH . CH(OH) . C_2H_5$, and β-ethylallyl alcohol, $C_2H_5 . CH : CH . CH_2(OH)$, the latter being new.—M. **Pariselle**: A new working method for the preparation of camphene. In the ordinary method of preparing pinene hydrochloride a yield of 55-65 per cent. is obtained: the yield can be raised to 75 per cent. by conducting the saturation with hydrochloric acid in two steps, with a two days'

interval. For the conversion of the chlorhydrate into camphene, the substitution of the sodium derivative of cresol for sodium phenate gives a purer product in nearly quantitative yield.—L. **Barrabé**: The continuity of the drift series of the eastern Corbières between la Berre and Narbonne.—F. **Delhaye** and A. **Salée**: The Central African *Graben* between Lake Tanganyika and Lake Albert Edward.—Adolphe **Lepape**: The relations between the radioactivity, temperature, and hydrogen sulphide of the springs of Bagnères-de-Luchon. Explanatory hypothesis.—MM. Allyre **Chassevant** and **Chouchak**: The measurement of the degree of ionisation of mineral waters.—de Montessus **de Ballore**: The local prediction of the weather.—V. **Lubimenko** and Mlle. O. **Szegloff**: The adaptation of plants to the duration of the bright period of the day. Green plants show a specific adaptation to the period during which they are illuminated.—Louis **Desliens**: Venous hæmodynamometry. Cardiac hæmodynamometry.—J. **Beyne**: The origin of the accidents caused by strong atmospheric depressions, and on the protection of the aviator against troubles of anoxhæmic order. For moderate reductions of pressure it is sufficient to supply so much oxygen that its partial pressure should be nearly 21 per cent. of an atmosphere. At low pressures, corresponding to high altitudes (more than 10,000 metres), even when the wants of the organism as regards oxygen are met, there are still troubles which must be ascribed to other factors.—Jules **Amar**: The organisation of work with the spade.—L. J. **Simon** and E. **Aubel**: Is pyruvic acid one of the terms of decomposition of glucose in the course of glycolysis? Pyruvic acid is not transformed by the elements of the blood. It is not produced during the process of glycolysis, and cannot be considered as an intermediary product of the decomposition of glucose into lactic acid.—Ch. **Bedel**: The toxic power of a polymer of hydrocyanic acid. The experiments were made on the polymer possessing the composition $(HCN)_4$. This was found to be much less toxic than hydrocyanic acid.—Albert **Berthelot**: Researches on pyruvic acid considered as a factor in anaerobiosis.—Maurice **Wolf**: The importance of calcium and potassium in the pathological physiology of cancer.—Charles **Pérez**: The castration of decapod Crustacea carrying Epicaridæ as parasites.

WASHINGTON, D.C.

National Academy of Sciences (Proc. Vol. 9, No. 5, May).—H. S. **Jennings**: (1) Crossing over and the theory that the genes are arranged in the chromosomes in serial order. Assuming that the genes are arranged linearly and that the occurrence of a break interferes in some way with the occurrence of another break at any joint within a certain distance, the cross-over ratios can be calculated. The theory is in accord with Morgan's work on Drosophila. (2) Some consequences of different extents of interference, in the crossing-over of the genes. For interference extending to a distance of 30 units (one unit being the distance between genes to give 1 per cent. of the crossing-over), no cross-over ratios greater than 50 per cent. are produced. With greater distances of interference, the cross-over ratios oscillate about 50.—J. A. **Detlefsen** and L. S. **Clemente**: Genetic variation in linkage values. In *Drosophila melanogaster*, the crossing-over ratio can be varied, but not necessarily to the same extent with regard to each part of the chromosome.—C. **Barus**: The displacements of the capillary electrometer, for progressive dilutions of the electrolyte. The negative meniscus is always displaced more rapidly than the positive meniscus, though the whole cycle is retarded by increasing dilution.—W. **Duane**: The transfer in quanta of radiation momentum to matter. It is assumed that the laws of the conservation of energy and momentum apply to these transfers. From a consideration of the reflection of X-rays by a crystal, equations expressing the momenta transferred to a crystal are developed. Applying dimensional reasoning, other expressions can be obtained which lead to the Braggs law of crystal reflection and the general equations of defraction of X-rays by a crystal. The reflection of X-rays characteristic of the chemical constituents of the crystal can be explained. The theory is also applied to the phenomena of light and radiation generally.—I. **Roman**: Mutual electromagnetic momentum and energy of a system of moving charges.—R. C. **Tolman**, S. **Karrer**, and E. W. **Guernsey**: Further experiments on the mass of the electric carrier in metals. A hollow copper cylinder was rotated inside a coil of 60 miles of copper wire (0·1 mm. in diameter), which served as the secondary of a transformer. The secondary was connected through an amplifier to a vibration galvanometer. The inertia of the electrons in the rotating cylinder causes them to lag and sets up an E.M.F. detected by the galvanometer. The deflections obtained were compared with those caused by the known E.M.F. accompanying transverse oscillation of the cylinder in the earth's magnetic field. The average value for m/e was $5{\cdot}18 \times 10^{-8}$ grams per abcoulomb, indicating that the mass of the carrier in copper is about the same as that of an electron in free space.—T. H. **Morgan**: Removal of the block to self-fertilisation in the ascidian Ciona. Eggs of *Ciona intestinalis* can be fertilised with sperm from the same individual if the egg-membranes are removed. The normal obstacle to self-fertilisation is the test-cells (between the membranes and the ovum) or something secreted by them; these cells are produced by maternal tissue and not from the ovum.—H. W. **Brinkmann**: On Riemann spaces conformal to Einstein spaces.

Large Scale Research in Abstract Science.

SEVERAL recent lectures and addresses have given prominence to the interconnexion between abstract science and industry and the marked influence of science on industrial progress. Among these may be mentioned two addresses by Sir J. J. Thomson, the first at the opening of the new laboratories of the General Electric Company at Wembley and the second from the chair as president of the Institute of Physics, the James Forest lecture of the Institution of Civil Engineers, and, most recent of all, the fourteenth Kelvin lecture of the Institution of Electrical Engineers by Prof. J. A. Fleming.

Prof. Fleming deals with problems in telephony, solved and unsolved, and illustrates in a remarkable way and with great knowledge and insight the consequences of scientific inquiry in the past, and the need for further researches in the future. Graham Bell died last year; Kelvin in 1876 had returned from the American Centennial Exhibition at Philadelphia to take the chair of Section A of the British Association at Glasgow, full of the invention of the telephone, which he described in his own inimitable manner, and Prof. Fleming, who forty-six years ago had been one of his audience at Glasgow, writes:

"In the year, therefore, following that of the decease of the illustrious inventor of the speaking telephone it is perhaps appropriate that the Kelvin Lecture should direct attention to some of the problems of telephony which have been solved or which remain unsolved."

The solved problems are sufficiently wonderful; the amplitude of the air vibrations in a just audible sound varies from about 10^{-8} cm. at a frequency of (say) 256 to rather more than 10^{-11} cm. at the highest audible frequencies, and minute motions such as these are impressed on the telephone diaphragm, translated into the variations of an electric current, transmitted to a distance, there amplified, communicated to the receiver, and from it to the observer's ear. Fleming's Kelvin lecture is a fascinating story of the many steps by which this has been achieved, showing how by degrees workers in various lands have each contributed their quota to the advance and made speech possible over 2000 or perhaps 3000 miles by aerial lines, 500 miles by underground, and 200 miles by submarine cables.

This progress rests on the theoretical investigation by Heaviside of the conditions for undistorted transmission, the application of this work, with successive improvements, by Pupin and Krarup and others to the loading of cables and the advances available by the use of the thermionic valve as an amplifier

and as the originator of "carrier" waves, rendering possible multiple telephony.

For the application of the valve as a rectifier of electric currents, we have to thank Fleming himself, while its whole action depends on the properties of the electron and the discoveries of J. J. Thomson. By the use of the valve as a repeater, many ingenious relays, the outcome of long and difficult investigations, have been placed in a secondary position; the lecturer explains in some detail how, by the selection of the suitable part of its characteristic curve, variations in the grid voltage can be impressed on the plate current and amplified by a transformer, while if another portion of the characteristic be employed, carrier wave multiple telephony is realised. In this "frequency filters" are employed—short circuits containing capacity and inductance which allow only those currents in which the frequency lies between certain limits to enter the line. The broad principles of the method are outlined thus:

"At one end of an existing long-distance telephone line used in the ordinary way for telephonic speech we can attach a certain number of modulating valves with their plate circuits coupled to the line with their appropriate transformers and filters. We can then generate by means of a number of oscillating valves high frequency currents of certain different frequencies and apply the electromotive forces due to these in series with the electromotive forces of low or speech frequency produced by ordinary carbon microphone transmitters so as to give to the grids of the several modulating valves carrier frequency plus voice frequency voltages. At the receiving end we separate out the several groups of oscillations by suitable band filters and apply the electromotive forces produced by suitable transformers to the grids of demodulating valves. In the plate circuits of these last valves we have coupled ordinary telephone receivers actuated by the voice currents disentangled by these demodulating valves from their respective carrier circuits."

Such has been the progress of less than fifty years. Fleming asks somewhat despondingly what is being done now in Great Britain. He refers to the laboratories of the great technical corporations of the United States, the American Telephone and Telegraph Company, the Western Electric Company, and the General Electric Company, giving an account of their activities in almost the same terms as those employed by Sir J. J. Thomson in his address to the Institute of Physics. "They retain," he writes, "the services of scientific investigators of the highest ability, who direct their attention not exclusively to problems of immediate commercial advantage, but look far ahead into the possible requirements of the future." Sir J. J. Thomson described two of these laboratories as seen by him during his recent visit to the United States. He found men at work on the most abstruse questions of physics—one need only mention Langmuir and the properties of the atom, or Coolidge and the investigations which led to the development of the Coolidge tube. There were numerous staffs of skilled assistants, some no doubt engaged in solving conundrums put to them by puzzled works managers, but many others searching deep into the secrets of Nature in the endeavour to find out new truths and to advance natural knowledge. Funds were practically unstinted, for the business directors of the works had found that by this means only could they extend the sphere of their activities and provide the dividends called for by their shareholders. In the United States abstract science has been made to pay.

Or to turn to another subject and another speaker. Quite recently the Wilbur Wright lecture, established by the Royal Aeronautical Society in memory of the American pioneer of aviation, was delivered in London by Prof. Ames, of the Johns Hopkins University. Prof. Ames is the chairman of the Executive Committee of the National Advisory Committee for Aeronautics of the United States, and directs the experimental work—full scale and model—of that committee at Langley Field. He has realised very fully the importance of an accurate knowledge of the air pressures on any part of aircraft undergoing manœuvres in the air; we were well aware of this, and years ago had done model experiments at the National Physical Laboratory, while at Farnborough apparatus for use in the air had been devised and some few experiments made. Prof. Ames showed slides illustrating in a most striking way the results obtained both on aeroplanes and airships, leading to information in the case of the latter which the Aeronautical Research Committee has pressed for many times, and which, had it been available in time, should have prevented the accident to the British airship R38.

Nor is this all: instruments have been successfully constructed which permit all the elements which contribute to a knowledge of the flight of an aeroplane—its velocities, accelerations, and the stresses to which its various parts are subject in the air—to be recorded during its flight. Instruments corresponding to some of these, such as the quartz-fibre accelerometer or the control force measuring stick, have been in existence at the Royal Aircraft Establishment for years; instruments corresponding to all have been planned and are in various stages of construction. In the United States they have found a man gifted with the knowledge to realise their need and with the authority to give effect to his knowledge. In England we have lagged behind.

So it is in other subjects; Great Britain is a small country, it is true, compared with the United States.

We owe much—in more senses than one—to our transatlantic kinsfolk, and we are piling up a debt which will prove more serious than the millions of the funding loan. What are we doing, what can we do, to reduce the load, to equalise the position ?

The General Electric Company has its new laboratories at Wembley finely equipped and guided in the proper spirit. "The question," Mr. Paterson writes, "is sometimes asked whether the laboratories undertake pure research or confine themselves to applied research," and his answer is that "the question is meaningless." "A research laboratory," he holds, "is not complete unless it contains members interested in almost every branch of science and provides facilities for these and also for other classes of work."

The National Physical Laboratory devotes much of the energy of its staff to abstract science, though telegraphy and telephony have not figured largely in its programme; these are catered for to some extent by the Post Office Research Laboratory at Dollis Hill. For metallurgical work we have the Brown Firth research laboratories and the Hadfield Laboratory at Sheffield; other firms have laboratories in which occasionally an investigation in pure science is carried out. But as a rule a work's laboratory is mainly occupied in controlling the normal product of the works, testing the materials supplied, and assisting the works managers in maintaining a proper standard.

Then there are the laboratories of the Research Associations established and in part financed by the Department of Scientific and Industrial Research; good and valuable work is being done by these, but the co-operative system has its obvious disadvantages, and in but few is abstract science pressed very far.

Our best hope for the future would seem to be with the universities, but here again the want of funds is an almost fatal handicap. "There is not," writes Prof. Fleming, "as far as I am aware a single university in this country which possesses the necessary equipment for conducting advanced experimental research in telephony and telegraphy"; and this is true of many other subjects.

Research is terribly expensive. We have always had men of the highest scientific originality who in the past have been pioneers in the advance of knowledge; we have them still, but somehow we fail to estimate their value; we are reluctant to furnish them with the means alone by which their natural gifts may be utilised. The application of science can be organised, and many steps have been taken in recent years to improve its organisation, but if we wish to utilise scientific progress to prevent waste and to increase the efficiency of industry we must support the solitary genius working often for a mere pittance in some university or college laboratory and devoting all his powers to unravelling a little further the tangled skein of Nature's mysteries. Success in the struggle depends on finding the right man and in affording him full facilities. We have the men; will our legislators who control the nation's purse see that facilities are not wanting for their work ?

R. T. Glazebrook.

An Epitome of Antarctic Adventure.

The Life of Sir Ernest Shackleton, C.V.O., O.B.E. (Mil.), LL.D. By Hugh Robert Mill. Pp. xv + 312 + 20 plates. (London: William Heinemann, Ltd., 1923.) 21*s.* net.

By common consent, Dr. Hugh Robert Mill, the author of "The Siege of the South Pole" and the friend and adviser of a generation of polar explorers, must be acclaimed the right man to tell us the story of the most brilliant career in modern Antarctic exploration. Not only has he long been the ablest chronicler and the most sympathetic critic of adventure and achievement in the southern seas, but he was also for long the friend and oftentimes the confidant of the subject of this biography. It was, therefore, with the keenest anticipation that we took up the book, anxious to see how a master hand would deal with a life so full of light and shade and a character compounded of such contrary impulses. The result is somewhat of a revelation, and whatever may be said in criticism of the book it must be acknowledged that the biographer has carried out his task worthily and has revealed to us the man as he was, fully and fairly. It was obviously no light task to reconcile the leader of magnificent sledge journeys with the unsuccessful dabbler in city finance, the platform lecturer, unconventional even to bluntness, with the sensitive lover of poetry, but it has been done with skill and understanding and the result will be to many a new Shackleton, undreamt of by those who knew but one of his many aspects.

The book is divided into three sections corresponding with somewhat indefinite periods in the life. In the first, styled "Equipment," we are introduced to a healthily mischievous boy with a taste for poetry and the sea, developing along normal lines into an efficient but scarcely an enthusiastic officer of the mercantile marine. So far the story is an ordinary one, and even to Dr. Mill's discerning eyes it foreshadows but little of the future. But then appears the nucleus round which his energy and ambition gathered. To the average reader the story becomes alive immediately

his future wife appears on the scene and stirs him to an incentive which in his own words at the time is expressed by the wish "to make a name for myself and for her," though as yet the sphere of fame had not been selected.

The chance came with his appointment to the *Discovery* expedition, and he seized it with both hands. Though but a junior officer he was selected for the most important journey, and under the hardest conditions he learnt the manifold tricks of the sledger's trade. How well he learnt them was to be seen some six years later when he took his own expedition south equipped with improvements on the *Discovery* arrangements in every direction. Compared to his own ventures, that of the National Antarctic Expedition was perhaps a little rigid in character, a little complex both in resources and aims, and a little embarrassed by committee control from home. We find Shackleton going to the opposite extreme in these matters, and generally with success, but we believe he had much to thank his first polar school for, if it can be called a school when all were learning and no one taught. The apprenticeship to Antarctic service is followed by shore jobs and a life varied in the extreme, a period through which the biographer takes us most successfully and indeed humorously, concluding the first part of the book with what must have been most excellent training, Shackleton's unsuccessful candidature for the general election of 1906.

Then comes "Achievement," the thrilling story of the multiple successes of his *Nimrod* expedition, a story hitherto told only in Shackleton's own words and therefore affording scope for the biographer to add many new and personal notes which explain actions formerly incomprehensible. Such, for example, was his repeated endeavour to seek a base on King Edward Land, not because his judgment selected it but because of a compact with Scott. How heavily this promise weighed upon him is seen in one of the gems of the book, a quotation from his letter written at the time of the decision—forced upon him by circumstances—to go back upon a promise which bound him too hardly. The journeys that follow, the triumphs of organisation and endurance which make up the history of that expedition, are well and fairly told. Records were broken in all directions, and from the popular point of view it was indeed the achievement of the whole career. From the point of view of the student of character and of the discerning reader of polar literature it was not the climax, which was to come eight years later. Served by his great ability, mental as well as physical, and aided by what he himself liked to call his luck, but which was largely his own foresight, he went magnificently far. Yet, in a sense, he went no farther than many another great leader has gone, with a similar fortitude, that is to say, to the limit of safety. To our mind the true ability of his leadership was not shown until he had gone farther than safety permitted and yet brought back his men in safety. None will dare belittle the triumph, but we believe that posterity will regard the management of the retreat of the *Endurance* party as his masterpiece and not the attainment of the heart of the Antarctic.

In the chapters which follow, headed "Popularity" and "Unrest," the biographer records faithfully the honours by kings and emperors, the triumphal progress of lecture tours, and the ups and downs of precarious finance. These things had to be recorded since they were part of Shackleton's life, but one is impatient all the time to get away from an atmosphere which never really suited him however brilliantly he shone in it on occasion.

Then comes the third part of the book, "Bafflement," a title true enough in a popular sense, for the rebuffs of fate were now well-nigh continuous, but scarcely comprehensive enough to indicate the real essence of this period of his life, the paradox of lasting fame arising from apparent failure. The story of the *Endurance*, already well, if tersely, told by Shackleton himself, gains colour in the hands of this master of narrative, and so too does our picture of the man, always at his best when with his back to the wall. Of polar travel it may be said more truly than of most ventures that any fool can get into a tight place but that it takes a man to get out of it again. Paraphrasing, we may say that most polar leaders have dared to the utmost as Shackleton did, many have achieved the utmost limit of endurance as he did, but few indeed have retreated in good order from an almost hopeless position. One has only to read the long list of ghastly retreats in polar history to imagine what might have happened, and then to admire the hand that grew firmer and the spirit that grew more courageous as the outlook grew darker. The chapter concluding the account of the *Endurance* expedition would have been an artistic ending to the book had it been possible. Not that great service was not yet to come, but the story now becomes diffuse with the welter of war, and the man is but one of many instead of at the head of a few. The story of the *Quest* inconclusive so far as the man is concerned, and is brief. It shows Shackleton with the same extraordinary capacity for organisation and the same magnetic personality ensuring support from unexpected quarters and rallying most diverse elements round him. At the same time it shows his judgment somewhat dimmed or perhaps merely harried by considerations

of finance and season, which hurried him off before his ship was really seaworthy.

The epilogue which closes the book is in Dr. Mill's very best style, and in many ways it gives us a clearer picture of the man than the recital of his deeds has done.

The book is a very notable addition to the library of Antarctic literature which the author has already enriched, and is singularly free from errors. We cannot miss the rare luxury of correcting Dr. Mill on points of fact, as for example on p. 68, where for "sea-ice" we should read "barrier-ice," or on p. 139, where for "2000 feet" given as the height of the gap between Mt. Hope and the mainland we should read "900 feet." Another slip of the pen is on p. 243, where the return journey of Mackintosh's party over the Barrier is described as "more trying even than that of Captain Scott." Otherwise all comparisons are wisely avoided, nor is an attempt made to assess the value of the life's work, which great as it was cannot be viewed as yet in its true perspective. More might have been said as to the character of the innovations made by Shackleton into polar work, from the point of view both of organisation and of methods of travel, though this was probably omitted as being too technical a subject for the book. If the first object of a biography is to enlist the sympathy of the reader for the man then the book is a signal success, for no one can read without emotion the vivid pictures of his doings and writings in so skilful a setting, and if excuse were needed for this biography at all it would lie in the fact that in the rapidly changing circumstances of polar organisation we may never again see such a man leading single-handed ventures to great success or triumphant failure.

F. DEBENHAM.

The Physics of the X-Rays.

Les Rayons X. Par Maurice de Broglie. (Recueil des Conférences-Rapports de Documentation sur la Physique. Vol. 1. 1re Série, Conférences 1, 2, 3. Édité par la Société *Journal de Physique.*) Pp. 164 + 5 planches. (Paris : Les Presses Universitaires de France, 1922.) 15 francs.

THE present volume is the first of a series of reports on physics edited by the French Physical Society and issued under the direction of an influential committee representing nearly a dozen institutions and societies in France. Each report is discussed at a number of conferences which are open to the public, and the report in its final form is published for the benefit of men of science, technicians, students, and others, who wish to make themselves *au courant* with the recent developments of the particular branch of knowledge in question. That such a scheme should be set afoot is not the least of a number of indications of a great scientific revival which our neighbours across the Channel are for their part endeavouring to stimulate.

A similar scheme has been initiated in the United States under the direction of the National Research Council, and already a number of volumes have been published. If we except the admirable reports published by the Physical Society of London, we cannot recall any similar organised endeavour in Great Britain to sum up the present state of knowledge in the various departments of science. Nevertheless, much has already been done by individual effort—as is perhaps the British way—and a number of British workers have already published valuable monographs on the various sections of physics with which their names are associated.

If the book before us is an earnest of the standard of attainment in the volumes still to come, there will be a warm welcome for the new series, which, we are informed, will deal with such subjects as the quantum theory, the electric arc, the structure of crystals, thermionics, etc.

The treatment adopted by the Duc de Broglie is a revelation of the amazing achievements of the X-rays in atomic physics, and provides many indications of the ramifications of the subject into many departments of physics and chemistry. For example, the opening pages contain an attractive discussion of Bohr's theory of the atom, Moseley's law of atomic numbers, and the part the quantum theory plays in the phenomena of radiation.

One is reminded that formerly the X-ray worker was unequipped with a precise means of sorting out the various qualities of X-rays with which he experimented. His only recourse was filtering through metal screens — a method which is relatively crude and ineffective for the purpose, and, indeed, served to mask a number of relations the real meaning of which can only now be appreciated. Nevertheless, by the insight of Barkla and others, several great and general truths were discerned, which laid the foundations of the subject as it has since developed.

A new era dawned with the discovery of the dispersion of X-rays by crystals. The new science of X-ray spectrometry sprang into being and at once turned to account the technique and precision of the older optical spectrometry. Valuable as the work on the analysis of the spectral lines of the optical spectra had proved to be, it was transcended in simplicity and potency by the newer spectrometry. To the literature on X-ray spectrometry the Duc de Broglie has himself contributed in notable measure, and his

account of the subject is correspondingly "alive" and authoritative.

Among much that calls for comment in this book is a good account of a variety of metal X-ray tubes which have so far been used chiefly in spectrometry. The recent researches which have filled the gap of 4 octaves between the former boundaries of the ultra-violet spectrum and the X-ray spectrum receive full attention.

One of the more recent triumphs of X-rays in the field of atomic physics is the work of the Duc de Broglie on the speed of the secondary electrons excited when X-rays fall upon matter. The speed was displayed by the method of the "magnetic spectrum"; and using X-rays of a specific wave-length, de Broglie was able to show that the secondary electrons arranged themselves into well-defined groups which had been ejected respectively from the K, L, M, etc. rings of the atoms of the material. These results, which receive simple explanation on the quantum theory and that of Bohr, have been confirmed in Great Britain by Whiddington, and widely extended at the Cavendish Laboratory by Ellis, who used radium γ-rays of much shorter wave-length than can at present be generated artificially. The present volume contains an interesting account of these enthralling investigations.

There are many valuable tables of wave-lengths, etc. in the book, and a number of plates showing some fine examples of X-ray emission and absorption spectra. At the end of each chapter there is a good bibliography. In accordance with French custom there is no index, but tradition is scouted by the provision of a serviceable stiff cover, a feature which will make its appeal in other countries.

G. W. C. KAYE.

Elementary Zoology.

Essentials of Zoology for Students of Medicine and First Year Students of Science. By Prof. A. Meek. Pp. xii+325. (London: Longmans, Green and Co., 1922.) 10*s.* 6*d.* net.

THE volume before us, intended for students of medicine and first-year students of science, is written by one who retains his belief in the "type system," and clearly has no sympathy with those who believe that this method of teaching, unless used with great discretion, is liable to do much to kill the student's interest in his subject.

The book consists of ten chapters, each devoted to one of the more important divisions of the animal kingdom. The chapter on Protozoa commences with short descriptions of Amœba, Paramecium, Vorticella, Cercomonas; these are followed by a section dealing with general considerations such as morphology, physiology, psychology, reproduction, symbiosis; and the chapter concludes with an account of important parasitic types—Opalina, Monocystis, Plasmodium, Trypanosoma. The descriptions of the various types are short and concise, but we notice a number of sentences which are liable to mislead the elementary student: such statements as that the trypanosome "progresses by the action of the flagellum which is *posterior*," that the recrudescence of malarial attacks is due to the female gametocyte developing parthenogenetically, that the fully grown "Plasmodium" becomes crescentic, require qualification or emendation.

The chapter on Cœlenterata deals with Hydra and Obelia, that on Platyhelmia with Distoma and Tænia, that on Mollusca with Anodonta, that on Annelida with Lumbricus and Nereis, that on Crustacea with Nephrops, that on Insecta with Blatta, Anopheles, Culex, and Glossina. We are glad to see our old friend Amphioxus accorded the dignity of a special chapter. The chapter entitled Pisces deals with the skate, and that entitled Amphibia with the frog. This is followed by a chapter on the development of birds and mammals, and the book ends with a chapter on Mammalia, dealing mainly with the rabbit.

As in the Protozoan chapter, so also in other parts of the book, we notice many statements that might with advantage be emended in a new edition. It is not accurate to say the gastrula is a stage in the development of *all* the metazoa. It would be wise to use the word solenocyte in the sense defined by its inventor. The expression "schizocœl *or* mesenchyme" is liable to lead the careless student to think these terms are synonymous. Such statements as "the myocœl develops a sclerotome," "the longitudinal valve [of the frog's conus arteriosus] is disposed in a slightly spiral direction from the right anterior aspect to near the left of the median line posteriorly," "the skeletal muscular system is derived from the . . . *myocœl* of the cœlomic mesoderm," "species of Rana are used for food . . . and large numbers are *employed* in zoological and physiological laboratories" (the italics are ours), are, to say the least, awkwardly expressed.

Such statements as we have quoted indicate that the book would have been the better for more careful revision before going to press. Notwithstanding such blemishes in detail we are of opinion that the book will prove useful to the class of student for whom it is intended. It is illustrated by numerous figures, somewhat rough in execution but for the most part clear and intelligible as well as accurate.

Arabia and Arab Alliances.

The Heart of Arabia: A Record of Travel and Exploration. By H. St. J. B. Philby. In 2 vols. Vol. 1. Pp. xxiii + 386. Vol. 2. Pp. vii + 354. (London: Constable and Co., Ltd., 1922.) 63*s*.

IN October 1917, Mr. Philby found himself the sole representative of Britain in the heart of Arabia on a mission which was organised, with the encouragement afforded by the initial success of the movement against the Turks on the Hejaz, to carry messages of goodwill to the ruling chief of Wahabiland. The co-operation of the latter was to be invited in giving effect to the Euphrates blockade against the Turks, and ultimately to launch a campaign against that very able ally of Turkey, Ibn Rashid of Hail. At the back of it there was no doubt some Utopian ideal of a united Arabia. The ruling chief of Wahabiland (which may be said to include all Najd, or Central Arabia, together with the coast province of Al Hasa bordering the Persian Gulf) was Imam Ibn Sa'ud of Riadh, and it was to Riadh that Mr. Philby's mission was directed, *via* Hofhuf, the capital of Al Hasa, from a port on the Persian Gulf coast opposite Bahrein.

At Riadh, Mr. Philby, who seems able to adapt himself most effectively, not only to Arab clothes, but also to Arab sentiment and the idiosyncrasies of the Arab people, and appears to be perfectly at home in the desert as in the town, secured the friendship of Ibn Sa'ud, and was certainly greatly indebted to that chief for his safety and success while traversing the country. The hospitality and almost invariable expression of goodwill which were extended to him throughout his travels were due not merely to the world-old traditions of the Bedouin but also to the influence of Ibn Sa'ud, who is obviously a most enlightened and competent ruler of a vast territory. At Riadh, Mr. Philby enjoyed the opportunity of giving us an excellent account of the city itself and of the character of the Wahabi faith as professed by its most ardent disciples—all of it most interesting and valuable information. But he failed to meet the British envoy who was to have brought from the west, from the Sharif of Mecca, messages of reconciliation with Ibn Sa'ud, who was known to be bitterly jealous of the Sharif. Nothing, indeed, roused the indignation of Ibn Sa'ud so effectively as that the Sharif of Mecca should assume the title of King of Arabia. All this, of course, is ancient history by this time, and the course of dramatic events which occurred more recently in the Hejaz is modern enough to be within the recollection of most of us. At the time, however, Mr. Philby's immediate movements were determined by the attitude of the Sharif, who simply declined to allow the British envoy to proceed to Riadh. In these circumstances, Mr. Philby decided to go to Taif himself and fetch him. In this, however, he was disappointed, although it led to a journey by the pilgrim road to Jeddah, passing within a measurable distance of Mecca and including a visit to Taif. The Sharif was absolutely hostile to any proposition of alliance with Ibn Sa'ud, and thus fell through the hoped-for unity between Central and West Arabia. Mr. Philby, who gives us a most interesting story of his travel by a route which is little enough known, was obliged to return to Mesopotamia by sea from Jeddah.

It was not long, however, before Mr. Philby found himself once again in Riadh, this time with the object of initiating an active campaign against Ibn Rashid, the Turks' ally at Hail. It was while he was waiting for Ibn Sa'ud to complete the preparations for this expedition (which afterwards proved more or less abortive and involved the death of that brilliant young explorer, Capt. Shakespeare) that Mr. Philby undertook what was by far the most interesting geographical exploration that has been made for many years in Arabia, which carried him as far south as the Wadi Dewasir, nearly to the edge of the great southern desert. He was still within the limits of the Riadh administration, but the influence of it grew weaker the farther he penetrated south, and it was at an important place in the Dawasir oasis, with the ominous name of Dam, that he encountered fanatical hostility, which, but for his tact and energy, might well have brought his career to an untimely end. Many points of especial interest attracted his close attention. The ruins at Kharj, the remains of the tombs of a long-forgotten race, are especially interesting in connexion with those at Bahrein, which were first examined and opened by Durand (Sir Edward of that ilk), whose description of them in the pages of the Journal of the Royal Asiatic Society is far more instructive than that of Theodore Bent (who followed him some years later), and points to a constructive resemblance with those of Kharj which cannot be accidental.

Mr. Philby devotes a chapter to destructive criticism of the delightful romances of Arabian adventure written by William Gifford Palgrave. Apparently he did not previously know (as certainly Mr. D. G. Hogarth, who questions Mr. Philby's conclusion, could not have known) that Palgrave had long been without honour among geographers of the Persian Gulf as a veracious narrator. Palgrave was a Jesuit father, true apparently to the traditions of his order, for, while we must render all honour to those early Jesuit missionaries who were the very first pioneers in the field of Asiatic geography, no one who has endeavoured to unravel their itineraries by the light of more modern determinations can fail to observe their skill in the

art of geographical embroidery. We might even repeat Mr. Philby's remark that some of their statements "bear no ponderable relation to fact."

"The Heart of Arabia" must be reckoned as a most valuable addition to the literary efforts that the mysteries of Arabia have called forth. There is always the danger in a work of this sort of descriptive narrative lapsing into the style of the official route report. This is most skilfully avoided by the author in his story of everyday happenings in a society which is as old as that of the patriarchs, and still exists in its patriarchal form. Mr. Philby is much to be congratulated on his remarkable experiences and his manner of telling them.

T. H. HOLDICH.

Our Bookshelf.

Flavouring Materials: Natural and Synthetic. By A. Clarke. (Oxford Technical Publications.) Pp. xxi + 166. (London: Henry Frowde and Hodder and Stoughton, 1922.) 8*s.* 6*d.* net.

THE manufacturer of foods and beverages, whose demands have created the infinite variety of flavouring materials now available, is a person with a remarkably catholic taste, since he appears to take into account anything with a flavour, from aloes to lemons, as possible materials for making his wares attractive. While laying the rose under contribution, he is apparently not averse from keeping scatole in his mind's eye as a possible means of titillating pleasantly the olfactory nerves of his clients. It is quite clear when such unpromising materials as some of these, not to mention colocynth and senna, which the average man regards as particularly nauseous drugs, can be seriously considered as ingredients in foods and beverages designed to be pleasant, that flavouring has become an art which requires its own experts and its own literature.

Mr. Clark's contribution, which he modestly describes as notes accumulated during a number of years' work in a technical capacity in the foodstuff and beverage trades, is a good beginning, and gives within small compass a mass of useful information regarding spices and condiments, the methods used in determining their quality, and the best ways of baulking the wily sophisticator who substitutes ground date or olive stones for powdered cinnamon or ginger. But spices in their natural state are no longer the only materials on which the flavouring expert can draw, and a considerable part of the book is devoted to a summary of the characteristics of purely chemical substances, extracted from essential oils or made in the factory. The particular part they can play in compounding flavours is described, and the things they may or may not be blended with are duly recorded.

The statements regarding each product are reasonably complete, and where further information is required references to original literature are given. Altogether the book is a good example of what technical literature of this kind should be, and though it would be easy to find points in it that are objectionable from a purely scientific point of view, they are not likely to mislead the reader for whom the book has been compiled.

T. A. H.

The Theory of Emulsions and Emulsification. By Dr. William Clayton. (Text-books of Chemical Research and Engineering.) Pp. viii + 160. (London: J. and A. Churchill, 1923.) 9*s.* 6*d.* net.

DR. CLAYTON's book is a fitting sequel to earlier issues of the series of "Text-books of Chemical Research and Engineering" to which it belongs. These have included volumes on molecular physics, the physics and chemistry of colloids, surface tension, catalysis, and catalytic hydrogenation. The skilful blending of advanced theory with advanced practice which characterises Dr. Clayton's book is therefore by no means a novel feature of these text-books. The author claims that his chief aim has been "to follow a logical line of development based on modern physico-chemical principles," and that "technical applications of emulsions have only been introduced either as illustrating some particular laboratory method on a large scale or because some important theoretical point is involved."

While, however, much of the book is actually devoted to theory, the practical aspects of emulsion-making and emulsion-breaking are very far from being neglected. Indeed, one of the most striking features of the later chapters is the large number of references to patents covering processes for carrying out these contrary operations. One of the most important applications of the process of emulsion-making is the homogenising of milk and cream. A process whereby new milk of 4 per cent. fat content acquires the appearance of a cream containing 8 per cent. fat, while a 15 per cent. cream becomes a good substitute for a 25 per cent. cream, has obvious attractions. The opposite process of breaking emulsions is an important operation in the initial treatment of crude mineral oils; but it is also important in the de-oiling of condensed steam, as well as in the more familiar operation of separating cream from milk and converting it into butter. The book contains a bibliography of nearly 200 papers dealing with emulsions and marks a new era in the scientific study of a subject which has very important practical applications.

T. M. L.

Mathematics for Students of Agriculture. By Prof. S. E. Rasor. Pp. viii + 290. (New York: The Macmillan Co.; London: Macmillan and Co., Ltd., 1921.) 16*s.* net.

EVERY indication that mathematics is assuming a more prominent position in the curriculum of students of agriculture is very welcome. The mathematical requirements of the agricultural student are roughly twofold. First, he requires a knowledge of simple calculations applicable to the routine problems of fertilisers, feeding stuffs, surveying, buildings, book-keeping, etc. Secondly, he very urgently requires an elementary understanding of statistical methods and probabilities applicable to the interpretation of experimental results. Prof. Rasor's book deals mainly with the first of these requirements. The value of the book to agricultural students approaching mathematics

for the first time would be enhanced if less prominence were given to formal definition and more to simple explanation, but there is no doubt about the usefulness of this book to the student who wishes expeditiously to revise and amplify previous work. It is concise, well indexed, and contains a large number of exercises. Some of the latter might profitably be revised. The statement in Exercise 5 on p. 13 that in a certain fertiliser "43⅝ per cent. is phosphoric acid (phosphorus)" will doubtless annoy the chemist. In the same exercise the student is asked to calculate how much acid phosphate containing 16 per cent. phosphoric acid is required, when mixed with cotton seed meal and kainit, to provide a mixture containing 43⅝ per cent. phosphoric acid. A practicable answer to this question might be the salvation of agriculture.

Unfortunately the use of American data and money units detracts from the value of the book to students elsewhere. N. M. C.

(1) *A Canadian School Geography.* By Prof. G. A. Cornish. Pp. xiv+450. n.p. (2) *The Canadian School Atlas.* Prepared at the Edinburgh Geographical Institute under the Editorship of Prof. G. A. Cornish. Pp. v+65 maps+16. n.p. (Toronto: J. M. Dent and Sons, Ltd., 1922.)

(1) THE best features of this work are the maps, illustrations, and practical exercises. For the rest the book is planned on somewhat orthodox lines. Too much is attempted in the space available, so that in places the book gives little more than a catalogue of uncorrelated facts. It is certainly most informative, especially with regard to Canada, to which a large part of the book is devoted, but on the whole the geographical outlook is wanting.

(2) The atlas was prepared in the first instance to be used with this text-book, but may easily make a wider appeal as a general reference atlas for use in Canada. It contains forty-eight pages of finely executed maps by Bartholomew and a full index. Fourteen pages are devoted to maps of Canada, of which the most populated parts are shown on scales of 1 : 2,500,000. The rest of the world is shown on small-scale maps, but there is a coloured orographical map of every continent. One improvement would be the addition of a larger scale map of India, but the atlas as a whole deserves high praise.

Nyasa, the Great Water: being a Description of the Lake and the Life of the People. By the Ven. William Percival Johnson. Pp. vii+204. (London: Oxford University Press, 1922.) 7s. 6d. net.

IN this volume, the Archdeacon of Nyasa has placed on record his knowledge of the lake and its people, among whom he has served for many years as a member of the Universities' Mission to Central Africa. In the preface, the Bishop of Oxford, with pardonable enthusiasm, says that it is unique and "a book which no student of 'backward' races can afford to leave unread." Its readers, perhaps, will not be prepared to go so far; but it is certainly a valuable and intimate study of the life and mentality, the customs, occupations, and beliefs of the Angoni, Wa Yao and Nyasa or Nyanza who live on the shores of the great lake Nyasa. The salient feature of the book is its keen insight into the native mind—a result which is achieved most markedly by means of the chapter of "village stories," in which the author has reported, in the words of the natives themselves, incidents of courage and helpfulness in the face of known and concrete danger. These he contrasts with the fear, leading to cruelty, arising out of the impalpable and unknown, which lies at the root of much of their religious ritual and belief.

Into the East: Notes on Burma and Malaya. By R. Curle. Pp. xxxi+224. (London: Macmillan and Co. Ltd., 1923.) 10s. net.

"CITIES (like persons)," says the author of this work, "have their idiosyncrasies that, slowly revealing themselves, layer upon layer, absorb you at last into their atmosphere," and goes on to ask what it is that the new-comer feels about Rangoon, in this particular instance, that to an inhabitant is second nature. Wherever his travels in the East have taken him, his purpose has been to seize the essentially differentiating quality in each place. He speaks of his book as a record of things seen and of things thought; but in the mind of the reader the latter will loom larger than the former, and in the retrospect, whether the author's words describe Colombo, Rangoon, Mandalay, the mining town of Kuala Lumpur, or the investiture of the Sultan of Perak with the K.C.M.G., it is their quality as an intensely personal record of impressions rather than as a statement of fact that will remain. In the end the author confesses himself baffled by the East, and its inscrutability and aloofness is perhaps the most vivid of the impressions he conveys to his readers. Mr. Joseph Conrad contributes a preface in which he discourses in characteristically alluring manner of travellers and of their works.

Abrégé de géographie physique. Par Prof. E. de Martonne. Pp. v+355. (Paris: Armand Colin, 1922.) 15 francs.

STUDENTS of geography will be glad to have this outline summary of M. de Martonne's well-known "Traité de géographie physique." The general plan is the same as in the larger work, but a new chapter has been added giving a sketch of the relations of human and physical geography. In order to make the treatment throughout the book as concrete as possible, the author has chosen under each heading the most striking aspects of the subject, wisely making no attempt to cover all the ground in a limited number of pages. The third section, "le relief du sol," is particularly lucid, and is illustrated by most instructive photographs and block diagrams. The bibliographical references to each section are well chosen, but why is there no index?

The Practical Electrician's Pocket Book for 1923. Twenty-fifth Annual Issue. Edited by H. T. Crewe. Pp. xci+571+Diary. (London: S. Rentell and Co., Ltd., 1923.) 3s. net.

A CHAPTER on "wireless" broadcasting has been added to this useful little book. Apparently some experimenters have difficulty in getting a good "earth," but the suggestion that they should get an old bath, solder the earth wire to it and then bury it, is in our opinion quite unnecessary.

Letters to the Editor.

The Quantum in Atomic Astronomy.

THE approach to the quantum by the path of energy, though historically natural and probably inevitable, is scarcely the simplest mode of presenting it to students. So long as assumptions or guesses have to be made, as a supplement to ordinary dynamics when applied to events occurring in the interior of an atom, it is best to make them nakedly, so as not to cloak their character; and then to let experience justify them, and hope for subsequent theory to explain them. This is a procedure after the manner of Kepler. The following brief summary, though inadequate as an exposition, is sufficient to indicate the main points in what I imagine to be a slightly clarified mode of presentation.

Bohr assumed (virtually) that, in a family of electrons revolving round a nucleus, the rate of sweeping areas, $r^2 d\theta/dt$ or $r^2\omega$ constant for any one orbit, proceeded discontinuously in arithmetical progression from orbit to orbit. This supplied a kind of Bode's law for the succession of satellite electrons, not at all dissimilar from the actual rough succession of planetary orbits round the sun provided that some of the possible orbits may be left empty; as they conspicuously often are inside the atom.

The recognised expression for twice the rate of sweeping areas, for inverse-square motion round a centre of force, is

$$\sqrt{\mu a(1-\epsilon^2)}\,;$$

and this, multiplied by the mass of the revolving particle, is its moment of momentum mpv, with p the perpendicular on the tangent; also called angular momentum, $mr^2 d\theta/dt$.

Bohr's assumption is that in the atom this quantity can only exist discontinuously in indivisible units or atomic portions, say A, of which only integer multiples are possible; so that it equals nA. One would gladly use the letter h for twice the rate of describing areas, as usual, had not the symbol been otherwise monopolised, in this connexion, by a quantity which, though approached differently, turns out on arrival to be nearly the same.

Our first equation, then, is that

$$m\sqrt{\mu a(1-\epsilon^2)} = n\mathrm{A}.$$

The time period of an inverse-square orbit is well known as

$$\mathrm{T} = 2\pi\sqrt{\frac{a^3}{\mu}}\,;$$

and this is our second equation.

So, combining these two equations, and ignoring the excentricity ϵ as an unimportant and provisional detail, we get at once for the angular velocity in a permissible circular orbit,

$$\omega = \frac{2\pi}{\mathrm{T}} = \frac{\mu^2 m^3}{n^3 \mathrm{A}^3}\,;$$

μ being, as usual, the force intensity, or acceleration at unit distance, namely in the electrical case, $\mathrm{E}e/m$, or $r^3\omega^2$. For accuracy, m should be interpreted throughout as half the harmonic mean, $\mathrm{M}m/(\mathrm{M}+m)$, because the revolution is round the common centre of gravity.

But, in accordance with Bohr's assumption, $n\mathrm{A} = mr^2\omega$; so that $n\mathrm{A}\omega$ is energy, mv^2, or say $2\mathrm{W}$.

Energy is therefore proportional to frequency; and we can proceed to identify $\mathrm{A}\omega$ with Planck's $h\nu$, and find that the relation between the introduced constants is simply $h = 2\pi\mathrm{A}$, because $\omega = 2\pi\nu$.

Further, by remembering that whenever a particle falls in towards an inverse-square centre of force it gains twice the energy which it can retain in a circular orbit (though no dynamical reason can be given for its half-stopping and occupying such an orbit and ejecting its surplus energy), we get for the energy radiated, on Bohr's second assumption that radiation only occurs when electrons drop from orbit to orbit, the difference between $\frac{1}{2}n_1\mathrm{A}\omega_1$ and $\frac{1}{2}n_2\mathrm{A}\omega_2$; or

$$\mathrm{W}_1 - \mathrm{W}_2 = \frac{\mu^2 m^3}{2\mathrm{A}^2}\left(\frac{1}{n_1^2} - \frac{1}{n_2^2}\right).$$

Whence Rydberg's spectrum-frequency-constant, defined as the constant part of $\delta\mathrm{W}/h$, comes out in the alternative forms,

$$\mathrm{N} = \frac{\mu^2 m^3}{2\mathrm{A}^2 h} = \frac{2\pi^2\mathrm{E}^2 e^2 m}{h^3} = \frac{\mathrm{E}^2 e^2 m}{4\pi\mathrm{A}^3}\,;$$

of which the last seems to have some advantages.

OLIVER LODGE.

The Resolving Power of Microscopes on Test-plates for Microscopic Objectives.

IN letters published in NATURE (September 1, 1921, p. 10; February 16, p. 205, and May 27, 1922, p. 678) on the above-mentioned subjects, I gave an estimate of the limit of microscopic resolving power; that is, of the least distance which must exist between two points in the focal plane if they are to appear as separate points in the image. I mentioned half a wave-length of the illuminating light as its approximate value. I have now, however, reason to believe that this is an overestimate and that $0{\cdot}7\lambda$ is nearer the mark. This is in agreement both with a re-computation of the illumination near the image of a point and with observations made on the test plates.

The image of a bright point in the geometrical focus of a lens consists, as is well known, of a bright disc surrounded by rings, the dark spaces between which indicate the positions where the integral difference of the optical length of the rays from any part of the dark ring to the corresponding distance from the geometrical focus is half a wave-length.

In Fig. 1 let O be the geometrical focus and $O\gamma$ the

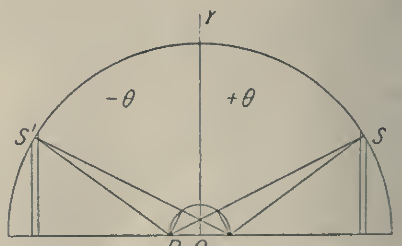

FIG. 1.

axis of the lens. Let SS' be a section of the spherical wave surface which by the action of the lens is converted into a second spherical surface with the same axis and with its centre at the conjugate focus. Let P be a point in the focal plane near O, and divide the surface SS' into elementary zones by planes to

which OP is normal. Consider a pair of such zones in latitudes $+\theta$ and $-\theta$ (taking the diametral plane as equatorial). Every point in each zone is at a constant distance from P, and the constant difference between PS and PS' is $2OP\sin\theta$. Assuming that the focal length OS is great compared with λ, and the conjugate focal length great compared to OS, then the difference of phase in the waves contributed to the image by each pair of zones is (if $OS=r$) $4\pi(r/\lambda)\sin\theta$. Putting A for the wave amplitude which would exist in the image if all the partial waves arrived in the same phase, and writing ϕ for $4\pi(r/\lambda)\sin\theta$, the actual amplitude at the geometrical conjugate focus of a point distant r from O is $A\int_{\theta_2}^{\theta_1}\cos(\phi/2)d\theta$, where θ_1 and θ_2 define the operative areas of the wave surface SS'. The value of A will be different for each pair of limits, but the ratio between the amplitude at O and that at r is $\int_{\theta_1}^{\theta_1}\cos(\phi/2)d\theta$. In computing this integral a table was formed for $\cos\phi/2$ between the limits 0 and 2 for r/λ, and 0 and $\pi/2$ for θ. Fair curves were drawn through the plotted values of $\cos\phi/2$ for each of the chosen values of θ (see Fig. 2)

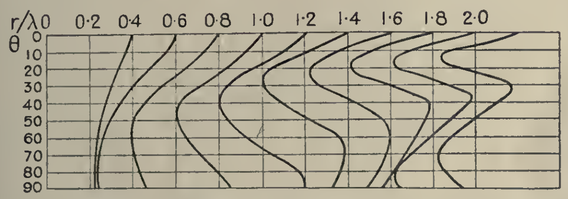

FIG. 2.—Horizontal lines measured from the curves to each of the principal verticals are the values of $\cos\phi/2$ (where $\phi=4\pi(r/\lambda)\sin\theta$) from $\theta=0$ to $\theta=\pi/2$, and the principal verticals refer to values of r/λ from 0 to 2.

and the algebraic area of the curves for various limiting values of θ was measured with a planimeter[1] (see Fig. 3). The intensities of the illumination are of course as the square of the amplitude.

When two or more luminous points in the focal plane are in proximity, the interference effects occurring between their ring systems are not independent of the nature of the illumination. If the luminous points radiate light proceeding from a single source, there is a definite phase relation among the emitted waves, and in this case the intensity is proportional to the square of the sum of the amplitudes; if, however, the points are self-luminous it is the sum of the squares which must be taken.

The change in the appearance in the field of a microscope when a point source is substituted for diffused light is very conspicuous.

The curves in Fig. 3 indicate that as the aperture of the lens is increased from 0 to 90° the diameters of the central disc and of the rings are reduced, as well as the relative brightness of the rings, and that when the whole hemisphere of the wave surface is operative the diameter of the central disc—*i.e.* the radius of the first dark ring—is a little greater than 0·4λ.

When the central rays are stopped out the diameter of the disc is still further reduced, but the brightness of the rings is greatly increased. Thus when only the marginal rays are effective the image of a single line will appear multiple.

It must be remembered that these curves only apply to points in the focal plane, and that the radii of the rings for points slightly out of focus are greater.

[1] For a somewhat similar purpose Airy (see his "Intensity of Light in the neighbourhood of a Caustic," Camb. Phil. Trans., vol. 6, pp. 379 *et seq.*) computed his table numerically by methods much more accurate, but also much more laborious, than the planimeter. The latter, however, is sufficiently good for the purpose of this note.

The lateral spectra which accompany the image of lines (which may be regarded as the envelope of the ring systems of a series of points) have a considerable effect on the appearance seen in the field of the microscope.

It is usually held that an object is in focus when the definition is sharpest. This, however, is not

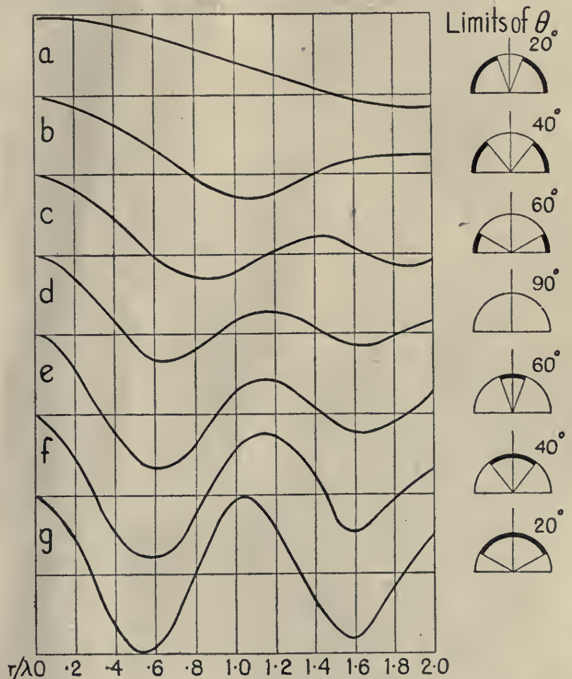

FIG. 3.—The curves are the algebraic integrals giving the areas included between the curves and verticals in Fig. 2 for each value of r/λ, and between the limits for θ indicated on each of the diagrams, namely:

Diagram	θ_1	θ_2			
a	20°	0	d	90°	0
b	40°	0	e	90°	20
c	60°	0	f	90°	40
			g	90°	60

The ordinates of the curves give the amplitudes of the resultant vibrations (expressed as fractions of the amplitude at the geometrical focus) at the various values of r/λ.

really the case. If bands of fine ruling in close proximity to one another are examined, it will be found that a separate adjustment of focus has to be made for each and that the best result is obtained when the focal adjustment makes the spacing of the lateral spectra the same as that of the lines of each band.

With ordinary test objects (diatoms, engraved lines, etc.) this effect is somewhat disguised owing to the thickness of the objects themselves, which is quite comparable to the wave-length, but in such test plates as I have described in my former letters, where the thickness of the film on which the lines are ruled is only 1/15 to 1/30 of a wave-length, the question of thickness does not arise.

The high resolving power which has been attained on diatoms and engraved lines should be attributed to variations of thickness in the objects, as these increase the rate at which the length of the optical path changes for points near the geometrical focus; *i.e.* for the variation of r. It is customary to mount such objects in media of high refractive index, which has the effect of exaggerating the optical depth of the grooves, etc., and it is worth notice that if an object has no thickness, or a thickness small compared to the wave-length and the only characteristic of which is a difference in opacity from place to place, the refractive index of the mounting medium is without effect on

the resolving power. In Fig. 4 let O and P be points in the focal plane. If the surrounding medium is air the optical length of the rays from O and P differ by $OP \sin\theta$. If O and P are covered by a uniform layer of a medium the refractive index of which is μ, the same rays in the medium make an angle θ' with the axis, where $\theta' \sin\theta' = \sin\theta/\mu$. The difference of optical length is then $OS\mu \sin\theta' = (OS\mu \sin\theta)/\mu = OS \sin\theta$, as it was in air.

This independence of μ does not extend to the case where one of the points O or P is slightly above or below the focal plane. If h is the elevation or depression in question, the difference of the optical lengths is $h(\mu \cos\theta' - \cos\theta)$, so that the difference increases both with μ and h. The quantity $0{\cdot}7\lambda$ suggested above as a limit to the resolving power of microscopes with respect to thin objects in the focal plane is a guess rather than an actual measurement. With the maximum angular aperture the radius of the first dark ring is a little greater than $0{\cdot}4\lambda$, which would indicate that objects must be separated by $0{\cdot}8\lambda$ before a really dark space appeared between their images; but the intensity of the light in the neighbourhood of the ring is very small, and doubtless the objects would seem as double at a less distance.

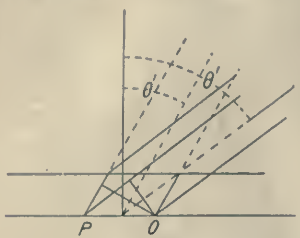

FIG. 4.

The experience, however, which I have had with fine lines ruled on thin films would induce me to place the limit at more, rather than less, than $0{\cdot}7\lambda$.

The Fluorescence of certain Lower Plants.

IT will, I venture to believe, interest some of the readers of NATURE to know that the Cyanophyceæ (Schizophyceæ) or blue-green algæ, the diatoms and some at least of the true green algæ among, or closely related to, the Pleurococcaceæ, are visibly strongly fluorescent when viewed ultramicroscopically, if the proper optical conditions are achieved. A much wider claim for the usefulness of the method might be made, but it will be unnecessary; for the moment, if any one who may be interested tries it, he will appreciate at once its many possibilities.

The optimum conditions are these: a dark-field condenser, preferably of the cardioid type, *thin* glass object-slides (0·8 mm. thick or less), preferably thin covers and a *dry* objective of any magnification. Water between the upper lens of the condenser and the slide answers every purpose, and is much more comfortable in extensive ultramicroscopy. The best light source, when one is studying colour, and this becomes of prime importance in this connexion, is a small arc; but generally speaking, a condensed filament, 400-watt lamp with a suitable condenser, answers every purpose. The thin object-slide and the glass-air interface of the cover are the essential features, since one is then able to focus the *reflected* hollow beam of light from the upper surface of the cover glass upon the object. It will be seen that in using the dark-field condenser in this manner we are reviving the idea embodied in the "spot lens" of Thomas Ross, in Wenham's air paraboloid (1850) with a similar spot lens, and in his glass paraboloid condenser of 1856 (Siedentopf, H., "Die Vorgeschichte der Spiegelkondensoren," *Zeitschr. f. wiss. Mikroskopie*, 24: 382-395, 1907). As these could be used only with a dry objective, the later effort was aimed at the result achieved in our present apparatus. It is evident from current published directions of manufacturers for work with the dark-field illuminator that the use of the reflected light cone is not contemplated. I refer especially to the specifications as to object-slide thickness. While not having the advantage of the magnification afforded by the oil-immersion, we gain very greatly in many features of the object-picture afforded.

One of the most important of these is that the blue-green algæ, when seen at the apex of the light cone inverted by reflection, afford their fluorescence colours. Some species are more readily recognised to fluoresce than others, but if the material be mounted in strong glycerin, thus obviating the scattering of light by internal surfaces either in the organism or in the surrounding mucilage, the cells are then seen to glow with a fervid light, orange or crimson according to the organism. Indeed, when glycerin is used, the fluorescence can be seen without making use of the inverted light cone, just as, according to Siedentopf, bacteria lightly coloured with a fluorescent stain ("Über Beobachtungen bei Dunkelfeldbeleuchtung," *Zeitschr. f. wiss. Mikroskopie*, 25: 273-282) may be seen with oil-immersion objectives. The object-picture then afforded has advantages of its own which need not be detailed here. Without glycerin, the fluorescence, even of those species which are most readily observed in this respect, is scarcely visible with oil-immersion objectives.

When seen mounted in glycerin, then, some species of Oscillatoria are crimson, as also are Cylindrospermum, *Anabæna Azollæ*, some species of Nostoc and of Chroococcus, Rivularia, and others; while other species of Oscillatoria and Nostoc are golden orange. *Chroococcus refractus* (I do not assert positive identification) appears a dull yellow, all these forms affording a most striking contrast to their appearance by transmitted light, that with which students of them are familiar.

I have found evidence that the pigment is in solution in minute vesicles (supporting in part Wager's conclusions, Proc. R.S., 72: 401, 1903). With death, it becomes adsorbed by the cytoplasm and the cells then appear blue (*e.g.* Nostoc). On examining material of *Nostoc commune* from China, which I have had in my possession some twenty years, I found the cells as strongly fluorescent as if fresh. The stiff gelatinous sheath appears light blue, perhaps also from adsorbed phycocyanin. When freshly mounted in glycerin, blue-greens hold their fluorescence for some time. I have an Oscillatoria kept thus for twenty days without loss of fluorescence. The old *Nostoc commune* lost its fluorescence in less than twenty-four hours, perhaps because it was already dead.

I have shown that the fluorescence is due to phycocyanin, rather than to chlorophyll, which, because of the "colloidal condition" in which it occurs in the living cell, has not been found visibly fluorescent. E. Raehlmann ("Neue ultramikroskopische Untersuchungen über Eiweiss," etc., *Pflüger's Archiv ges. Physiologie*, 112: 128-171, 1906), it is true, thought that he could see chlorophyll fluorescence with the ultramicroscope, but he used suspensions or emulsions, and with these I have obtained similar results. With suitable means, the fluorescence microscope, for example, the fluorescence of the living chloroplast can be observed, but one can scarcely persuade oneself that it can be seen

with the ultramicroscope as ordinarily used. One can, I think, see a dim suggestion of the fluorescence colour in isolated chloroplasts (Elodea), and in the chloroplast of Spirogyra, but when *in situ* the multitude of reflecting surfaces produces so much transmitted light that the fluorescence is masked by the green coloration.

It was, therefore, of no small interest to find also that the pigment in the oil vacuoles of the diatoms, pale greenish-yellow by transmitted light, is also visibly deep red fluorescent when viewed in the manner above described. Glycerin must be used as a mounting medium. Examined thus, the fluorescent pigment is seen to fill vacuoles, large and small. I have found that this pigment is not destroyed at the temperature of boiling water, whereas phycocyanin changes at about 60° C. irreversibly, and loses its fluorescence. It may be the phycocyanin-like pigment found by Bocat (through Czapek, "Biochemie des Pflanzen," 1: 601) in Navicula, which, as a matter of fact, has two large fluorescent vacuoles and usually two small ones, one near each end of the cell.

Scenedesmus glows with a deep red light, as also a small species of Raphidium (or closely similar organism). I have found further evidence of fluorescence in other green forms, notably an ulvaceous one.

Many beautiful results will reward the microscopist who will use the method. Especially, one can scarcely contemplate the remarkable irradiance of these lowly plants without realising anew the importance of the problem of the physiological significance of fluorescence. In a paper presented at the recent meeting of the Royal Society of Canada, I have endeavoured to discuss the matter in its more general bearings. The immediate purpose is to direct attention to a means of increasing the usefulness of the dark-field condenser.

FRANCIS E. LLOYD.
McGill University, Montreal, June 1.

Dr. Kammerer's Lecture to the Linnean Society.

I AM very sorry to differ from my friend Prof. MacBride, but it is impossible for me to agree with some of his remarks on Dr. Kammerer's recent lecture (NATURE, June 23, p. 841). I did not assert that Dr. Kammerer made "childish mistakes which would disgrace a first-year student in biology." I expressed my opinion that it was not correct to state that the ovary of Salamandra is enclosed in a membrane while that of the bird is not. I fail to see why Dr. Kammerer's statement should require to be translated into modern technical language. It is a somewhat serious suggestion that he cannot express his ideas in such language for himself, and if that be so, it supports my criticism that in some respects his statements were not in accordance with the present state of biological knowledge.

I cannot, however, accept even Prof. MacBride's description of the condition of the ovary of the bird as correct (and I dissected out the ovary of a common hen to-day, not for the first time). The ovary of the bird is almost as completely invested by peritoneum as that of the Salamander, not only on its ventral surface but on its lateral surfaces also, and it is not largely retroperitoneal. I agree that the ovary of the bird is more difficult to remove in its entirety, because it is sessile on the peritoneum, and not connected with it by a membrane, and still more because its attachment is close to the great post-caval vein, so that it is difficult to remove the part by which it is attached without cutting into the vein. To be strictly correct, the narrow membrane which attaches the ovary to the wall of the body cavity in Salamandra is not a mesentery, as Prof. MacBride calls it, because that term means a membrane connected with the intestine.

It would serve no useful purpose to reply to other points in Prof. MacBride's letter. He refers me to Dr. Kammerer's "long paper." But I was dealing with the lecture as delivered and printed, which in my opinion failed to show that Dr. Kammerer had an adequate conception of the range of knowledge, the completeness of evidence, and the validity of reasoning, required to establish the conclusions he asks us to accept. I am not, of course, suggesting any deception on Dr. Kammerer's part—except self-deception. Lamarckian doctrine has often suffered more from the indiscretion of its advocates than from the attacks of its enemies.

The British Journal of Experimental Biology.

THOUGH British workers have made some of the most signal contributions to the morphological aspects of zoology, and names like those of Romanes, Bateson, Doncaster, and Geoffrey Smith will always be distinguished for pioneer discoveries in the experimental field, Great Britain at the present moment compares very unfavourably with other countries in facilities for the publication of researches in experimental biology, especially on the zoological side. There is no single journal devoted wholly or mainly to the subject, with the exception of the *Journal of Genetics*, which of course only covers a portion of the field. We have in Great Britain nothing to compare, for example, with the *Journal of Experimental Zoology*, the *Biological Bulletin*, and the *Journal of General Physiology* in America, or with the *Archiv für Entwicklungsmechanik* in Germany and the French *Archives de morphologie expérimentale*. Nor have we any biological journal which makes it a regular practice to publish articles of a general nature summarising and discussing critically recent additions to knowledge, as in the *American Naturalist* and the *Referaten* of several continental journals.

In the absence of an adequate medium of publication in Great Britain, experimental biologists do not know sufficiently what work is in progress, with the natural result that there is overlapping; that experimental inquiry, lacking a satisfactory channel of expression, may fail to exert an influence essential for the further development of biology in Great Britain; and that younger men will tend to migrate from the zoological laboratories to associate themselves with departments of human physiology. Biological science is at present passing through a period of transition: on one hand, it is becoming increasingly clear that the problems of evolution can no longer be dealt with adequately from the traditional morphological and descriptive point of view of zoology; on the other, the adoption of experimental methods by the general zoologist is opening up new fields of research and making it possible to study more readily the nature of many fundamental biological processes, such as fertilisation, development, sex and heredity, which have been too often neglected by traditional physiology. In the words of a distinguished morphologist, there is a growing tendency "to return to the practice of earlier days, when animal physiology was not yet divorced from morphology."

We believe that the time has now come when it is possible to issue a British journal devoted to general biology, in particular to experimental research and to

investigations bearing directly upon experimental problems. We have, therefore, arranged with Messrs. Oliver and Boyd, Edinburgh, to undertake the publication of the *British Journal of Experimental Biology*, the first number of which will appear in September next. The new journal will receive communications in comparative physiology, experimental embryology, genetics, and animal behaviour, as well as cytological, morphological, and histological contributions bearing on current experimental problems. It will also publish by invitation authoritative résumés of recent progress in various fields of inquiry. Any relevant original contribution will be considered for publication.

Inquiries may be addressed to the Animal Breeding Research Department, the University, Edinburgh.

An Einstein Paradox.

THE fallacy of the argument put forward by Prof. R. W. Genese, in the former part of his letter in NATURE of June 2, p. 742, lies in his supposing that the time t at which K sees the light-signal from L is related to the time t', when K_1 sees the same signal, by the transformation

$$t'=\beta(t-vx/c^2),$$

where $\beta=(1-v^2/c^2)^{-\frac{1}{2}}$.

If we suppose the light-signal to be emitted from L at a time T (in K's system) and T_1 (in K_1's system), then

$$T_1=\beta(T-vx/c^2), \quad . \quad . \quad . \quad . \quad (1)$$

$$x_1=\beta(x-vT), \quad . \quad . \quad . \quad . \quad (2)$$

where $x=KL$, $\quad x_1=K_1L$.

Suppose now that K receives the signal at time t (in his system) and that K_1 receives it at time t_1' (as judged by K_1's system). Let t_1 be the time in K's system corresponding to t_1' in K_1's system. Then

$$t=T+x/c, \quad . \quad . \quad . \quad . \quad (3)$$

$$t_1'=T_1+x_1/c, \quad . \quad . \quad . \quad . \quad (4)$$

and $t_1'=\beta(t_1-vx/c^2). \quad . \quad . \quad . \quad (5)$

Substitution from (1) and (2) in (4) gives, with (3),

$$t_1'=\beta t(1-v/c),$$

and comparison with (5) shows that $t \neq t_1$.

A little careful consideration of these equations will now show that the supposed paradox does not arise for the case $x_1=0$. J. T. COMBRIDGE.

King's College, Strand.

Multiple Temperature Incubator.

IN the course of some experimental work on insects which we have been carrying out, it was necessary to have a large number of constant temperatures. As it was impossible to have a complete incubator for every temperature, an incubator was designed by Mr. T. W. Kirkpatrick and myself to give a continuous series of constant temperatures.

The principle used is the conduction of heat along an insulated metal bar between two constant temperatures. In practice one of these is an ice-box and the other a hot water bath at any convenient temperature. Between the two is a bar, tube, or trough of metal, four to twelve feet long, which has holes bored at close intervals throughout its length. Both copper and aluminium have been used for the conducting bar. The whole is well insulated to avoid the influence of the daily temperature change.

The apparatus has exceeded our expectations and would probably be of great use to investigators in other fields. Full details with scale drawings and temperature charts will be published shortly in a Bulletin of the Ministry of Agriculture of Egypt, which will be sent to any one who is interested.

C. B. WILLIAMS.

Ministry of Agriculture (Entomological Section), Cairo, June 20.

Phosphorescence caused by Active Nitrogen.

IN order to prepare aluminium chloride for atomic weight determination, I burnt pure aluminium metal in a current of pure dry chlorine. Before starting the reaction, pure dry nitrogen was passed through the apparatus to expel the air. After this has been attained, the flow of nitrogen was stopped and a slow current of pure dry chlorine was allowed to pass over the metal. Since the pure dry gas reacts very slowly with aluminium at ordinary room temperature, the tube containing aluminium was heated to about 500° C. After the completion of the reaction, the aluminium chloride formed and a quantity of uncombined metal was cooled in a very slow stream of nitrogen. As the red heat ceased, a bright green phosphorescence appeared in the reaction tube surrounding small pieces of corroded uncombined metal.

This phenomenon was excited the next day when the synthesis was continued, and the last traces of chlorine were removed by nitrogen. In both cases the afterglow disappeared after about one minute. Two important facts should be added, namely:

(1) The reaction tube—free of chlorine—with aluminium chloride and the metal was heated again to the same high temperature, and nitrogen was passed over while the whole system was cooling down. The bright green light did not appear. Nothing of this kind of light was visible when the pure metal was heated alone. This is a sufficient proof that the observed afterglow in the former cases was not caused by a trace of any known or unknown impurity of the metal used.

(2) The phenomenon was not observed during the synthesis of aluminium bromide which was carried out by Prof. Th. W. Richards and me in the same manner, and with an aluminium of the same origin.

In NATURE of May 5, p. 599, and May 26, p. 705, were published letters by Prof. E. P. Lewis and Mr. W. Jevons describing phosphorescence caused by active nitrogen. These letters, particularly the second, by Mr. W. Jevons, suggested to me that the afterglow of aluminium left in the reaction tube was very probably caused by active nitrogen. The presence of traces of active nitrogen was caused by the violent reaction of the chlorine left in the tube with the aluminium metal. This reaction activated some of the nitrogen passed over the metal. When, however, all the chlorine was expelled and the contents of the reaction tube were heated as in the case described above, no phosphorescence appeared. H. KREPELKA.

Department of Inorganic Chemistry, Charles' University, Prague, Czechoslovakia.

The Cryogenic Laboratory of the University of Toronto.

By Prof. J. C. McLennan, F.R.S.

SHORTLY after the commencement of the War it became evident that if helium were available in sufficient quantities to replace hydrogen in naval and military airships, losses in life and equipment might be very greatly lessened.

It was known that there existed in America supplies of natural gas containing helium in varying amounts, and Sir Richard Threlfall, as a result of preliminary calculations that led him to believe that this helium could be extracted at a cost that would not be prohibitive, proposed that the Board of Invention and Research of the British Admiralty should undertake an investigation of the matter. As a result of this proposal the writer was asked by the Board to determine the helium content of the natural gases of Canada. This survey was carried out in the winter of 1915–16, and it was found that from 10,000,000 to 12,000,000 cubic feet of helium could be obtained per year from the natural gas of the Bow Island supply near Calgary, Alberta.

In the autumn of 1917 the Admiralty sanctioned proposals to proceed with an attempt to extract this helium, and in the summer of 1918, after exhaustive experiments had been made, a plant was designed for the purpose. This apparatus was constructed and installed at Calgary and was operated from September 1919 until April 1920. In the course of this operation of the plant, considerable supplies of helium of high purity were obtained and it was shown that the estimates of Sir Richard Threlfall as to the cost of production were amply verified.[1]

During the winter of 1919–20 proposals were put forward by the writer to use the helium extracted at Calgary for scientific purposes. These met with approval, and financial grants were made for the liquefaction of helium by the Honorary Advisory Council for Scientific and Industrial Research of Canada, by the University of Toronto, and by the Carnegie Foundation for Research. Some apparatus was also loaned by the Admiralty and by the Air Ministry of Great Britain. With these grants special apparatus for liquefying air, hydrogen, and helium was constructed and its installation in the Physical Laboratory of the University of Toronto was completed towards the end of 1922. In the preliminary operation of the plant, special facilities in the way of power were provided by the Hydro-Electric Commission of Ontario and by the Hydro-Electric Commission of Toronto.

[1] Trans. of the Chem. Soc. vol. 117, p. 923, 1920.

Helium was liquefied with the equipment for the first time on January 10 of this year, and the Cryogenic Division of the Physical Laboratory was formally opened on January 24, when demonstrations were given of the production of liquid air, liquid hydrogen, and liquid helium. Series of experiments were also shown illustrating the uses of these liquefied gases.

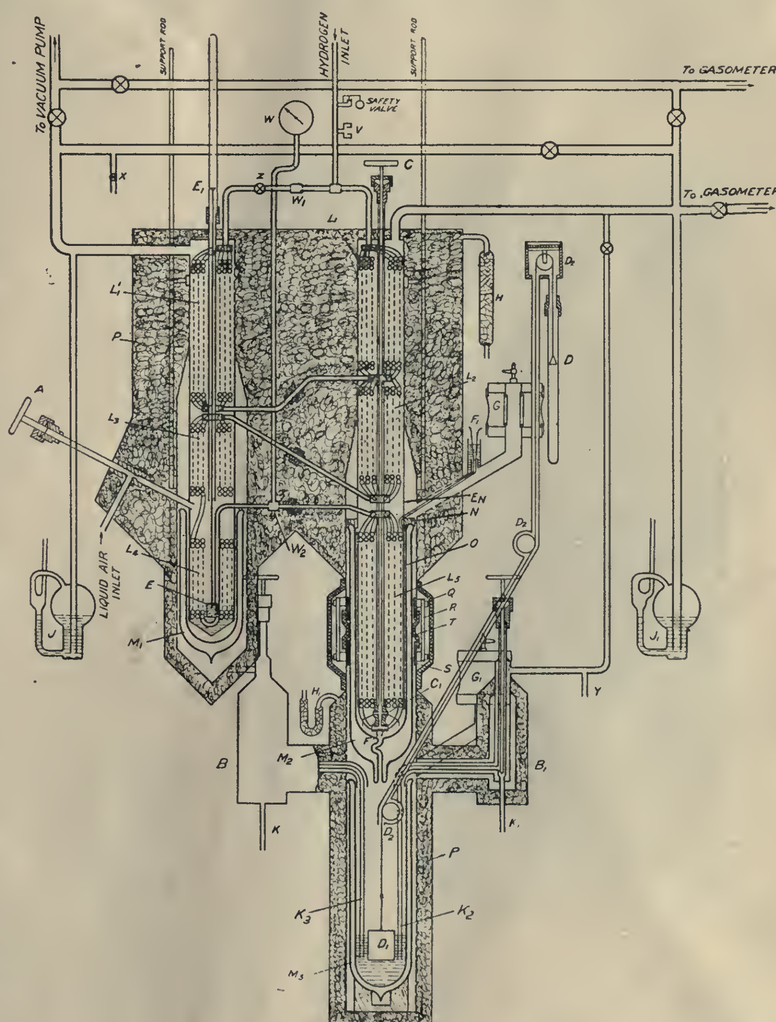

FIG. 1.—Hydrogen liquefier.

Liquid Air Apparatus.

The apparatus constructed for the liquefaction of air consisted of a 40-kilowatt alternating current motor, a Norwalk compressor of the three-stage type, a water cooler, carbon dioxide purifying towers, and one of L'Air Liquide's machines having a capacity of producing 20 cubic metres of oxygen per hour. This machine was provided with valves which enabled one to isolate the rectification column from the oxygen heat exchanger, permitting the operation of the apparatus as a machine for liquefying air or as one for producing gaseous oxygen. The column was also

provided with modifications for the extraction of the rare gases from the atmosphere. In operating this apparatus the air was compressed to 40 atmospheres, and in a series of tests it was found that about 300 kilograms of liquid air could be made per day. With such a supply of liquid air available, ample provision was made, it will be seen, for meeting the needs in regard to liquid air of all departments of the University.

Liquid Hydrogen Apparatus.

The equipment for liquefying hydrogen included a four-stage belt-driven compressor built by the Burckhardt Engineering Works of Basle, Switzerland. Its cylinders were water-cooled, had a forced lubrication,

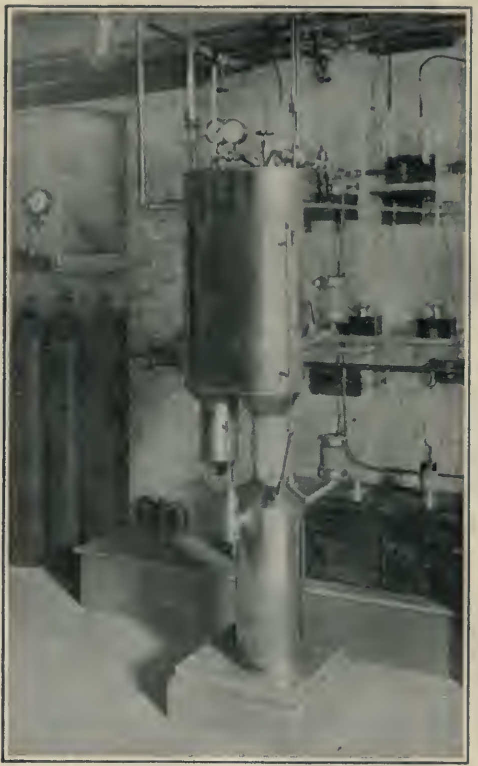

Fig. 2.—Hydrogen liquefier (as installed).

and were fitted with steel piston rings. The pistons were all in line and constituted one shaft. The gas was cooled after each compression by means of a number of heat exchangers immersed in a tank of running water. The compressor was constructed so as to prevent any loss of gas, and with this end in view, the piston rods were provided with special stuffing boxes in which the packing was sealed with oil contained in specially designed holders.

The space behind each piston as well as the safety valves was directly connected with a gasometer and through the latter to the intake of the compressor. The compressor had a capacity of 60 cubic metres of free gas per hour and required a motor of 30 kilowatts to operate it when delivering at 200 atmospheres pressure. Twenty litres of water per minute were disposed of by the heat exchangers.

The hydrogen liquefier is shown schematically in Fig. 1 and as it was installed in the laboratory by Fig. 2. The regenerator coils indicated were similar to those used in the well-known Hampson apparatus for liquefying air. In operating the liquefier, hydrogen specially purified was compressed to 150-200 atmospheres and cooled to −205° C. by means of liquid air boiling under reduced pressure.

The compressed hydrogen passed successively through the coils L_1, L_1', L_2, L_3, L_4, and L_5. The coils L_1 and L_1' were arranged in parallel and the valve Z served to regulate the proportion of gas that went through each of them. This ensured the proper interchange of heat between the oncoming compressed gas and the outgoing low-pressure vapours. The coils L_1, L_2, and L_5 were cooled by gaseous hydrogen returning to the gasometer from the expansion nozzle C_1, and the coils L_1' and L_3 by the evaporated air drawn off by the vacuum pump. The coil L_4 was partly immersed in a bath of liquid air held in the flask M_1.

The valve A served to admit more liquid air from the reserve supply whenever the indicator E_1 of the cork float E showed that it was required. To add to the efficiency of the liquefier, the expansion coil L_5 was provided with a close-fitting German silver envelope which when properly wrapped with flannel permitted a good junction to be effected between the inner wall of the silvered vacuum flask M_2 and the coil. This ensured that the expanded gas passed over the closely wound tubes of the coil and so brought about a good exchange of heat.

The liquid hydrogen as it formed passed through the opening in the bottom of the flask M_2 and was collected in the silvered flask M_3. The float indicator D, D_1, D_2, served to show the level of the liquid in this collecting flask. The weight D was connected with the thin German-silver float D_1 by means of a silk thread running over three pulleys D_2 provided with jewel mountings. The valves B and B_1 were used for drawing off the liquid. These were arranged so that they could be pre-cooled by cold gaseous hydrogen as it was returned to the gasometer. The stuffing boxes and screw thread of the valves B, B_1, C and A were so arranged that they were not exposed to cooling and in this way the danger of a freeze-up was eliminated.

The insulation of the apparatus was specially studied. Vacuum flasks were used where possible, and wherever parts were cooled below the temperature of liquid air they were surrounded by an atmosphere of dry hydrogen or by a partial vacuum in order to avoid unnecessary condensation. All parts were constructed of German silver where it was an advantage to do so on account of its low thermal conductivity. The entire apparatus was packed in natural wool and enclosed in a thin brass case that was sealed except for the drying tubes H and H_1. These tubes served to equalise the internal and external pressures on the case and at the same time prevented water vapour from entering and condensing inside. Fig. 1 shows plainly the arrangement for supporting the apparatus together with the scheme of the pipe connexions. Mercury traps J and J_1 served to protect the apparatus at all times from any sudden but moderate excess of pressure, while the large rubber safety valves G and G_1 served to accommodate any sudden but violent

increase of pressure such as might arise from the breaking of the flask M_3.

In operating with the hydrogen liquefier it was found necessary to remove all gaseous impurities from the gas. The commercial hydrogen used was made electrolytically and was found to contain as much as 1·5 per cent. of oxygen and 0·1-0·3 per cent. of nitrogen. To purify this gas it was passed through a high pressure bomb filled with palladiumised asbestos. This bomb was heated electrically to about 400° C., and at this temperature the palladium acted as a strong and robust catalyser. The water produced by the union of hydrogen with the oxygen present was taken up with caustic potash. The hydrogen obtained after this preliminary purification was again purified by passing it through a specially constructed apparatus provided with coils cooled with liquid hydrogen, but to make the liquid hydrogen for carrying out this purification it was necessary to operate the hydrogen liquefier with the hydrogen subjected to the preliminary purification only. A few litres only could be made in a run before stoppage occurred, and this was used to effect the final purification of a certain quantity of the gas.

By repeated operations of this character a supply of about 100 cubic metres of highly purified hydrogen was gradually accumulated, and with it long runs of the liquefier were made without any stoppage occurring. To conserve this original supply of pure hydrogen care had to be taken during a run to store up all gas from the vaporised hydrogen and to use residual supplies of liquid hydrogen to purify additional quantities of the gas so as to make up losses.

In liquefying hydrogen as well as helium, it was necessary in order to avoid losses so far as possible to operate in a closed cycle that included a gasometer, the compressor and the liquefier. In a number of actual runs with the apparatus described above, no difficulty was experienced in making from 10 to 15 litres of liquid hydrogen an hour, and in one particular run as much as 50 litres of liquid hydrogen was accumulated.

LIQUID HELIUM APPARATUS.

The helium used in the experiments was obtained from the natural gas of the Bow Island district near Calgary, Alberta, in the year 1919–20, and had been kept since then safely stored in steel cylinders at about 150 atmospheres pressure. An analysis by means of absorption with cocoanut charcoal showed the gas in different cylinders to be about 90-95 per cent. helium. The chief impurity was nitrogen, with a varying percentage of methane and other gases. Tests made by chemical absorption and explosion methods gave no indication of hydrogen being present.

The preliminary purification of the helium was effected by cooling it at a pressure of 150 atmospheres to −205° C. by means of liquid air boiling under reduced pressure. Under these conditions a large percentage of the impurity was condensed and drawn off. This partially purified helium was passed at high pressure first through a bomb filled with copper oxide and palladiumised asbestos maintained at a temperature of 400° C., and then through heavy copper tubes filled with cocoanut charcoal and immersed in liquid air. This cycle of purification proved to be satisfactory, for during the liquefaction process there was no evidence at any time of any blocking of the expansion valve of the liquefier or of the very small capillary tubes that made up the expansion coil.

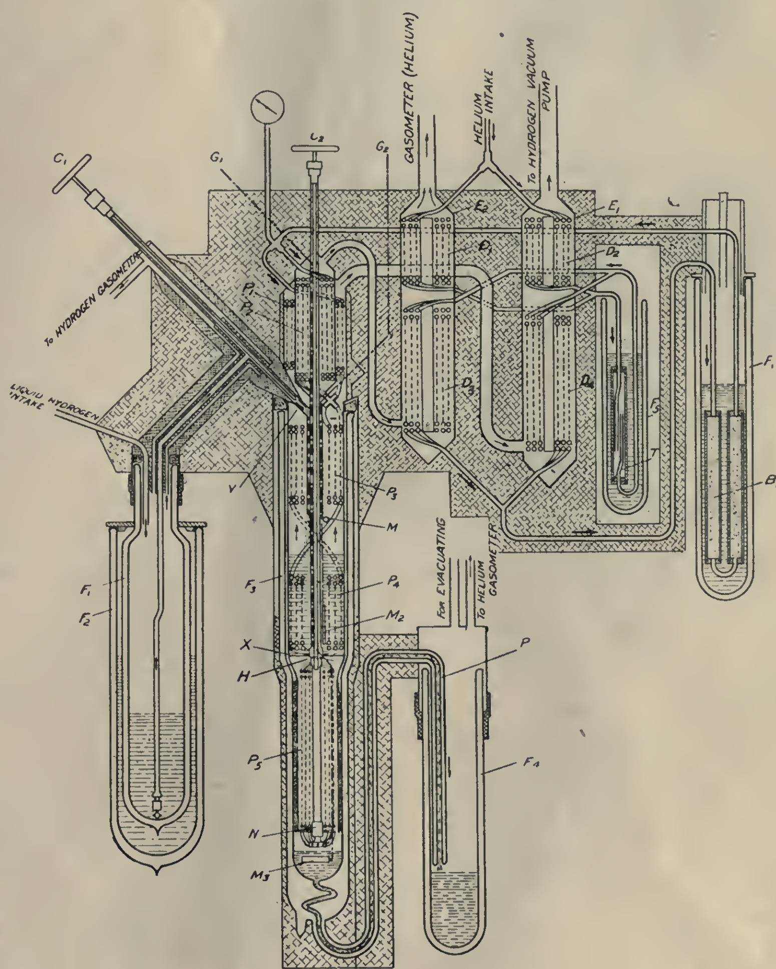

FIG. 3.—Helium liquefier.

In the design and construction of the helium liquefier, special attention was given to problems connected with the heat capacity and heat insulation of the various parts of the apparatus. The liquefier is shown diagrammatically in Fig. 3 and the manner in which it was installed in the laboratory is shown in Fig. 4.

In the operation of the liquefier the manner in which the helium entered the apparatus is shown in the

diagram. It passed successively through the coils D_1, D_2 and D_3, D_4 arranged in parallel. It then entered

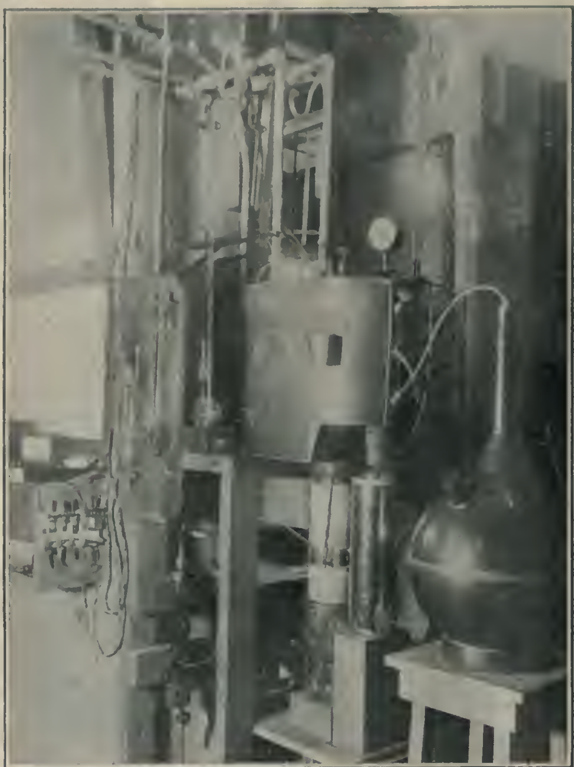

Fig. 4.—Helium liquefier (as installed).

the coils P_1 and P_2 also in parallel, and afterwards passed successively through the coils P_3, P_4 and P_5. The coils D_2, D_4, P_1 and P_3 were cooled by the cold hydrogen vapour as it was drawn off by the hydrogen vacuum pump, and the coils D_1, D_3, P_2 and P_3 by the expanded helium that issued from the region about the expansion valve on the way to the gasometer. The coil P_4 served for the final pre-cooling of the compressed helium and was immersed in liquid hydrogen boiling under a pressure of 6 cm. of mercury. A trap T was provided, by means of which the gas was freed from the last traces of oil or water vapour from the compressor. The tubes B_1 were made of copper and were filled with cocoanut charcoal. They were cooled with liquid air during the liquefaction process with a view of absorbing any gaseous contamination introduced during the operation of the cycle. The level of the liquid hydrogen in the refrigerator surrounding the coil P_4 was determined by means of copper-constantan thermo-couples, and alternatively by helium gas thermometers with reservoirs at M and M_2, that were connected with a mercury manometer by fine steel tubing G_2.

The liquid hydrogen from large vacuum-surrounded metal containers was first transferred to the unsilvered flask F_1, that was protected by an outer silvered flask F_2 containing liquid air. This flask F_2 was provided with two unsilvered vertical observation strips, one on either side, so that the level of the liquid hydrogen in F_1 could be seen directly. The valve C_1 controlled the intake of the liquid hydrogen from F_1 to the refrigerator, and the valve C_2 with its corresponding spindle controlled the expansion nozzle at the bottom of the coil P_5. The efficiency of the regeneration properties of the expansion coil P_5 was assured by fitting closely over it a very thin german-silver envelope soldered at X to the bottom of the german-silver liquid hydrogen container. With this arrangement the expanded helium was forced to go through the interstices of the expansion coil in order to enter the holes H in the tube surrounding the expansion valve spindle.

The temperature of the region beneath the expansion nozzle was determined with a helium gas thermometer provided with a german-silver reservoir at M_3 and a connecting steel capillary tube G_1. The protecting vacuum flask F_3 was provided with a specially designed siphon tube P. This tube was double-walled and was protected by silvering and by an intervening vacuum in the same manner as a Dewar flask. The flask F_4 could be made either totally silvered or partially silvered with a plain portion at the bottom. In the latter case it was protected by a plain vacuum flask containing liquid hydrogen, and this in turn by a plain vacuum flask containing liquid air.

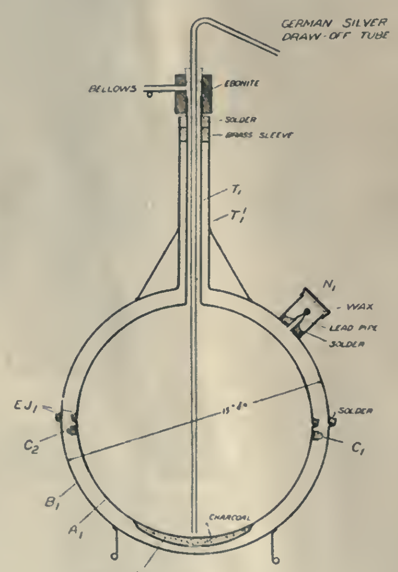

FIG. 5.—Metal container for liquid air.

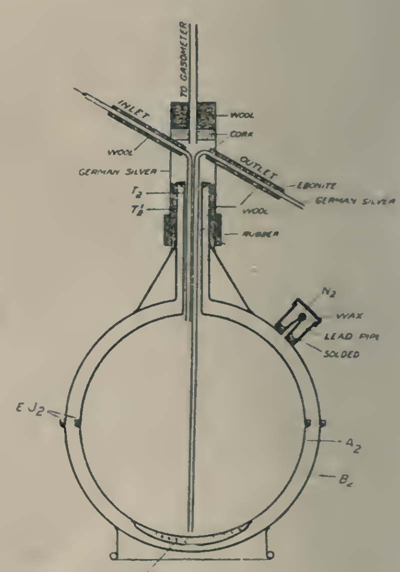

FIG. 6.—Metal container for liquid hydrogen.

These figures illustrate the types of metallic vacuum Dewar Flasks found useful in handling large quantities of liquid air and liquid hydrogen. They were made of polished spun copper. In assembling them, extreme precautions, it was found, had to be taken to remove not only the air but also all water vapour from the space between the spherical surfaces. A container of 25 litres capacity when well constructed did not lose so much as a kilogram of liquid air per day.

In constructing the hydrogen and helium liquefiers great care was taken to see that all the complicated

tubing was free from holes and much time was consumed in the work of eliminating leaks. The whole apparatus was, however, completed towards the end of 1922 and, as stated, was used early in January of this year for the production of liquid helium. The helium was compressed with an enclosed Whitehead torpedo compressor, and the liquefier was found to give the best results when run at a pressure of only 40 atmospheres.

Before attempting to make liquid helium all parts of the liquefier were cooled as low as possible with liquid air, the piping being cooled by circulating through it helium that had been previously cooled to liquid air temperature. When this precaution was taken, it was found that liquid helium could readily be made with a moderate amount of liquid hydrogen supplied to the refrigerator surrounding the coil P_4. In our experiments less than 10 litres of liquid hydrogen sufficed to produce more than a litre of liquid helium.

I wish to take this opportunity of acknowledging my indebtedness to Prof. Kamerlingh Onnes of Leyden, the pioneer and outstanding authority in research at liquid helium temperatures. He not only assisted me very materially through correspondence and conversation, but also furnished me with drawings of the installation at Leyden.

It is hoped that with the cryogenic equipment now available at the University of Toronto, a series of low-temperature researches will be organised shortly for workers who for any reason may not find it convenient to go to Leyden to carry out investigations.

Rickets in Vienna.

A NUMBER of summary publications have made readily available the rapid advance in our knowledge of rickets in the last few years since Mellanby in 1918 brought forward serious evidence implicating a deficiency of fat-soluble vitamin A, and Huldschnisky in 1919 showed that the bone-lesions in children could be cured by ultra-violet light, and McCollum and his co-workers in 1921 demonstrated that the disease could be conveniently produced in rats by defective diets. Last year the Medical Research Council published the survey by Prof. Korenchevsky [1] of the experimental aspects and Dr. J. L. Dick [2] brought out a useful book on the human disease and its history. More recently an admirable survey of the whole question by Prof. E. A. Park [3] has appeared, and there has now been added a full account of the results of the expedition under Dr. Harriette Chick,[4] sent in 1919 to Vienna by the Lister Institute and the Medical Research Council, to study deficiency diseases under the conditions of almost experimental accuracy and precision afforded by the generous hospitality of Prof. v. Pirquet's Kinderklinik.

The report shows, beyond any reasonable doubt, that the incidence of rickets may be determined by diet, and that vitamin A plays an important part; that it may be prevented and cured by cod-liver oil; that it may be cured by sunshine or the rays from a mercury-vapour lamp, and that a diet which in summer is adequate for young infants may, in winter gloom, permit its development. From the practical point of view, the facts provide most of what the sanitarian needs: a proper supply of cod-liver oil, or its equivalent in vitamin A, and of sunshine, or its equivalent in ultra-violet light, will prevent rickets, and a deficiency of one may be made good by a larger supply of the other. What is at present unknown is how much vitamin A in the more customary forms of milk and green vegetables is wanted to give the same result as teaspoonfuls of the far more potent cod-liver oil. But there is no longer any excuse for there being two schools of thought disputing for a hygienic and a dietetic ætiology respectively: as usually happens in such controversies, it turns out that both parties are right.

In the larger matter of the circumstances which condition the proper and regular growth of bone the results are of great interest. Granting an adequate supply of the necessary materials—and of these calcium and phosphorus are the most obvious, and their importance has already been examined by direct experiment—vitamin A is necessary: with enough of this, rats grow satisfactorily in the dark (Goldblatt and Soames, *Biochemical Journal*, vol. xvii., 1923, p. 294). Ultra-violet light of about 300 $\mu\mu$ has much the same effect, and it was at first supposed, rather naturally, that it operated by causing a photo-synthesis of vitamin A. But rats on a diet grossly deficient in vitamin will grow normally under the influence of ultra-violet light only for a time: in the end, if no vitamin A is provided in the food, growth ceases, and the animals go downhill. Evidently light enables the animal to make the most economical use of such store of vitamin as it may have in its body or of any small amounts it may receive in its food: light can only partly replace vitamin, and if there is abundance of vitamin, light has no favourable influence on growth. In the same way vitamin makes a short supply of calcium or phosphorus go further, so that, while any of the three may be a limiting factor, up to a certain point of deficiency it is the sum (or product) of calcium phosphate and vitamin which is the effective determinant. Light *per se* is not a limiting factor, but may become the determinant under conditions of defect in the others.

Obvious as is the effect of ultra-violet light on the naked human skin, it is a little difficult to believe that it can act directly on the general body surface of hairy animals such as rats: "man is naked," as Richard Owen remarks, "and is the only terrestrial mammal in that predicament." It is, therefore, satisfactory to find it shown that air irradiated by the mercury vapour lamp is effective in promoting growth in rats, as Kestner showed it was in hastening the regeneration of blood lost by hæmorrhage: such air, in the absence of ultra-violet light itself, will also cure rickets in children. It does not seem to be known as yet whether radiation of the body surface with exclusion of radiated air

[1] Medical Research Council Special Report Series, No. 71. The Aetiology and Pathology of Rickets from an experimental point of view. Pp. 172+18 plates. (London: H.M Stationery Office, 1922.) 4s. net.
[2] London: W. Heinemann.
[3] *Physiological Review*, vol. iii., 1923, p. 106.
[4] Medical Research Council Special Report Series, No. 77. Studies of Rickets in Vienna 1919–22 (Report to the Accessory Food Factors Committee appointed jointly by the Medical Research Council and the Lister Institute). Pp. 203+14 plates. (London: H.M. Stationery Office, 1923.) 7s. 6d. net.

from the lungs has any influence on bone-growth, nor on what constituent of the radiated air the effect depends.

It is possible that the mechanism in man is not quite the same as in hairy animals, and that direct irritation of the skin by sunshine—to which some clinical observers attach considerable importance—does much the same as irritation of the bronchial mucous membrane, which is embryologically the same as skin, by ionised air or traces of ozone or nitric oxide. If this is so, irritation of the skin by means other than ultra-violet light should have the same effect—which is perhaps the explanation of Dr. Mayo's observation on rickets in 1674 that "scabies or itching contributes much to its cure." Little is known about what has been called the "internal secretion" of the skin beyond the fact that irritation may lead to changes in other parts of the body. Thus a blistering agent applied locally may considerably increase the susceptibility of the whole skin to the same substance.

Current Topics and Events.

In an article which appeared in Nature of July 21, p. 101, the view was expressed that the constitution of the committee of the recently formed British Empire Cancer Campaign was not such as would command the respect of *bona fide* workers on the cancer problem. While our article was in type, a meeting of the Grand Council of the British Empire Cancer Campaign was held, and contrary to the original intention, and no doubt as a result of informed public opinion, it was decided to appoint a scientific advisory committee of ten members. It was urged, however, that an attempt should still be made to preserve the balance between scientific and clinical workers. On the following day the annual meeting of the Imperial Cancer Research Fund was held under the presidency of the Duke of Bedford, who expressed himself as in entire agreement with the attitude which had been adopted by the executive committee of the Fund in resisting the danger of being drawn into the British Empire Cancer maelstrom. In an admirable review of the work of the campaign he directed attention to the crass ignorance which prevails with respect to the work which has been done by the Fund, and he laid great stress on the necessity for the British Empire Cancer Campaign to be in the hands of those acquainted with work already done, as this is the only means of avoiding useless repetition and preventing the waste of funds obtained from a generous and sympathetic public.

Congratulations are due this week to the Rev. Dr. T. G. Bonney, who celebrated his ninetieth birthday on Friday, July 27, having been born at Rugeley, Staffordshire, in 1833. The son of a clergyman, Dr. Bonney was the eldest of ten children. Educated at Uppingham, he was sent to St. John's College, Cambridge, where he graduated twelfth wrangler, and soon after accepted a post as mathematical master at Westminster School. It has been said of him as regards his early education, that "mathematics had impressed upon his mind the real necessities which are demanded by a proof; classics had assisted him to cultivate a literary gift; and travel had taught him facts at first hand." Ordained a priest in 1858, in the following year he was elected to a fellowship at St. John's. In 1877 Dr. Bonney took up the professorship of geology in University College, London, a post he held until 1901. For four years secretary of the British Association, he was president of the Geological Society, 1884–86, and president of the British Association at the Sheffield meeting of 1910, giving an address on some aspects of the glacial history of Western Europe. In 1889 he was awarded the Wollaston gold medal of the Geological Society. In allotting the gift the then president remarked that in Dr. Bonney's hands the microscope had been a valuable adjunct to field-observation and had been chiefly applied to detect the secrets of those rocks which, possessing no organic remains to betray the tale of their origin, had hitherto baffled inquiry into their early history.

On June 16 the Polish Academy of Sciences and Letters at Cracow celebrated, in the presence of the President of the Polish Republic, the fiftieth anniversary of its foundation. The Academy originated in 1873, evolving from a scientific society which has existed in Cracow since the beginning of the nineteenth century. The first president of the Academy was Józef Majer, a man who rendered valuable service to the cause of science in Poland; he was succeeded by Count Stanislas Tarnowski, for many years professor of the history of Polish literature in the Jagellonian University; Prof. Casimir Mozawski, a philologist of European renown, is now president. The Academy is divided into three classes—devoted respectively to philology and linguistics, to historical and social science, and to mathematical, physical, and natural science. In conformity with the statutes, the Academy consists of 60 active Polish members, 36 foreign and 96 corresponding members. The publications of the Academy since 1873 are numerous; they include 206 volumes of the Transactions of the Classes, 50 volumes of the Proceedings (the Cracow *Bulletin International* is well known to scientific men all over the world), 10 volumes of a beautiful publication intended to promote the cultivation of the history of art in Poland, 146 volumes of transactions of various committees appointed to elucidate problems in the history of Polish language, literature, and civilisation, 90 volumes of publications on Polish political and economical history, 57 volumes of the Transactions of a special committee investigating the physiography of Poland (meteorology, geophysics, mineralogy, and geology, systematic botany and zoology), 36 volumes of the Transactions of the Anthropological Committee, 10 volumes of the "Polish Encyclopædia" (in course of publication), and more than 300 volumes of various other works separately published. The Academy possesses a fine

library (with many valuable MSS.), remarkably rich physiographical and anthropological collections, a permanent scientific station at Paris (4 Quai d'Orleans), and a quasi-permanent station (chiefly for historical investigation) at Rome.

DR. A. E. H. TUTTON is to be congratulated on the completion of a laborious piece of work which he set himself in 1890. This was the investigation of the isomorphous relations existing between the sulphates and selenates of the alkali metals and ammonium and the double salts of these with certain divalent metals. It is noteworthy that this work has been performed in his spare time, and for the last twelve years in Devonshire. In his presidential address to the Devonshire Association at Salcombe on July 10, he gave a general review of the results attained and of their bearing on the structure of crystals and of atoms. In all, seventy-five salts have been worked out in the greatest possible detail and their crystallographic and other constants determined with the highest degree of accuracy, for which purpose several elaborate instruments were specially designed. In eighteen groups, in which potassium, rubidium, and cæsium are the replacing elements, it is repeatedly and conclusively proved that the constants vary with the atomic weights of these elements, and consequently also with their atomic number and atomic diameters. The dimensions deduced for the structural units of these crystals have since been amply confirmed by the X-ray analysis of crystal-structure. But the more direct and very carefully made observations will be of permanent value for testing theories of the future.

AT a meeting of the Board of Directors of the Manchester Chamber of Commerce held on July 16, the following resolutions were passed unanimously: That, whereas the word "gallon" is at present capable of different interpretations (due to the difference of about 20 per cent. between the Imperial and the American gallon), and whereas the alternative use of the litre is already sanctioned by law throughout the commercial world, it is desirable that all traders—especially those concerned in overseas trade—should promote uniformity of trading practice by employing the litre as the sole unit of capacity. (*N.B.* If those engaged in any special trade desire to retain the word gallon it should be in the form of a "new gallon" equal to 4 litres, which would approximately represent the average value of the present conflicting gallons.) That, whereas the word "ton" is at present capable of different interpretations according to whether the "long," "short," or "metric" ton is intended, and whereas the use of cwts., quarters, stones, and other local weights involves further confusion and loss of commercial efficiency, it is desirable that all traders—especially those concerned in overseas trade—should express the weights of goods in pounds only, and convert such pounds when desirable into equivalent weights in kilograms.

OWING to the work of redecorating the rooms of the Chemical Society, the library will be closed during the entire month of August, and in accordance with the usual practice will close at 5 P.M. daily on September 1-17.

THE following have been elected honorary members of the Society of Chemical Industry: Prof. C. F. Chandler, United States; Prince Ginori Conti, president of the Italian Chemical Society; M. Paul Kestner, president of the French Society of Chemical Industry; Prof. Joji Sakurai, Japan; and Sir Dorabji J. Tata, India.

THE annual autumn meeting of the Institute of Metals will be held in Manchester, on September 10-13. The meeting will open with the second annual autumn lecture, to be delivered by Sir Henry Fowler, on "The Use of Non-ferrous Metals in Engineering." Papers will be read and discussed on the mornings of September 11 and 12, and visits to works and places of interest in the neighbourhood have been arranged.

APPLICATIONS for Yarrow Research Professorships will be received by the Secretaries of the Royal Society until October 1 next, as the president and council of the society will in the autumn consider the appointment of one, or possibly more, professors who will be expected to devote their whole time to research in the mathematical, physical, chemical, or engineering sciences. Further particulars are obtainable from the Assistant Secretary of the Royal Society, Burlington House, Piccadilly, W.1.

AT the annual general meeting of the Royal Veterinary College held on July 17 the Duke of Connaught, president of the College, announced that, in conformity with the recommendation recently made by the advisory committee on Research in Animal Diseases, the Development Commission, through the Ministry of Agriculture, has made a grant of 25,000*l.* for the erection of a new research institute in connexion with the College. It is hoped that the new premises will be ready for occupation in less than a year.

AT the recent meeting of the trustees of the Beit Memorial Fellowships for Medical Research, the honorary secretary, Sir James Fowler, presented a review of the work of the trust for the period 1910–1923. Since the foundation of the trust in 1909, seventy-nine fellowships have been awarded. Originally the annual value of the fellowships was 250*l.*; this was increased to 300*l.* in 1919 and to 400*l.* in 1920. In 1922 they were reclassified as junior, fourth-year, and senior, with the values, 350*l.*, 400*l.* and 600*l.* respectively. Of the first fifty fellows elected, two have been made fellows of the Royal Society, eight have secured professorships, four have become directors of research institutes, and most of the remainder are holding responsible appointments.

THE Ramsay Memorial Fellowship Trustees have made the following elections to fellowships and renewals of fellowships for the Session 1923–24, the place of research where stated being given after the

name of the fellow elected: *British Fellowships* (300*l*.): Dr. S. Coffey, at University College, London; Dr. A. F. Titley; and Dr. R. W. Lunt, at University College, London. *Glasgow Fellowships* (300*l*.): Mr. T. S. Stevens and Mr. J. A. Mair, both at the University of Glasgow. *Norwegian Fellowship* (5400 kroner): Mr. G. Weidemann, at the Biological Laboratory, University of Cambridge. *French Fellowship* (100*l*. plus 14,000 francs): Dr. H. Weiss, at the Royal Institution (Davy-Faraday Laboratory). *Netherlands Fellowship* (300*l*.): Mr. J. Kalff. *Danish Fellowship* (300*l*.): Mr. K. Højendahl, at the University of Liverpool. Since the institution of the Ramsay Memorial Fellowship Trust in 1919 twenty-one fellowships, not including those announced above, have been awarded.

THE thirty-fourth congress of the Royal Sanitary Institute will be held at Hull on July 30-August 4 under the presidency of the Right Hon. T. R. Ferens. The proceedings will be divided among four sections dealing with sanitary science, engineering, and architecture, maternity and child welfare, and personal and domestic hygiene respectively. In addition to the sectional meetings a number of conferences of representatives of sanitary authorities, medical officers of health and similar workers have been arranged. Sir Alexander Houston will lecture to the Congress on "A Pure Water Supply," and among the subjects to be discussed at the various meetings are the prevention of tuberculosis and cancer, the curative value of ultra-violet rays, the nutritive value of milk, heliotherapy, the smoke evil, and food-poisoning. Several Government departments and also foreign and Dominion Governments are sending delegates. Visits will be paid to local institutions, water-works, and factories, and a Health Exhibition showing apparatus and appliances relating to health and domestic use will be open throughout the meeting.

THE 104th annual meeting of the Swiss Society for Natural Sciences will be held on August 30–September 2 at Zermatt. This will be the fifth occasion when the Society has met in the Canton of Valais. The work of the meeting will be divided into fifteen sections as follows: (1) Mathematics, (2) physics, (3) geophysics, meteorology, and astronomy, (4) chemistry, (5) geology, mineralogy, and petrography, (6) botany, (7) zoology, (8) entomology, (9) palæontology, (10) anthropology and ethnology, (11) medical sciences, (12) history of medicine and the natural sciences, (13) veterinary medicine, (14) pharmacy, and (15) engineering science. In addition to the sectional gatherings, there will be general discussions which will be addressed by distinguished men of science. Among the topics thus dealt with will be: Phylloxera in Valais, by Dr. H. Faés, director of the Federal Viticultural Station, Lausanne; earthquakes in Switzerland, by Dr. A. de Quervain, of the University of Zurich; and the geology of the neighbourhood of Zermatt, by Prof. E. Argand, professor of geology, palæontology, and petrography in the University of Neuchâtel. The following officers have been appointed for the meeting: *President*, Rev. C. M. Besse; *Vice-President*, Dr. J. Amann; *Treasurer*, M. E. de Riedmatten, and *Secretary* M. A. de Werra, of Sion, Valais.

THE National Research Council of the United States has issued as a Bulletin an account of the State Research agencies of Illinois other than the University, prepared by Prof. L. D. White of the University of Chicago. These agencies spent 40,000*l*. on research during the fiscal year 1921-22, employing 230 scientifically trained workers. The smallness of the grant is due largely to the claims for research being subject to review by non-professional administrators who have no very definite understanding of the aims of research. The salaries paid to the research workers are small, and the best men are attracted by the posts open to them in industry. While managing officers receive from 500*l*.-1000*l*. per annum, engineers, geologists, naturalists, and bacteriologists from 300*l*.-700*l*., and medical officers and psychologists 350*l*.-570*l*., chemists receive only 250*l*.-450*l*. per annum. The report recommends that research officers should be relieved of routine work, that the University should be recognised as the central research agency, and that the salary scale should be equal to that maintained in the University for persons of similar professional attainments.

THE Årsbok for 1922, Part II., of the Swedish Meteorological Service gives full details, accompanied by maps, of the precipitation in Sweden. For each month of the year are given a summary of the fall for each province, with a comparison of the mean average fall, and the details of several hundred stations throughout the country. For each station are given the total fall in the year, the total for the wettest day, and the number of days with precipitation more than certain amounts. There are maps of the monthly and annual distributions of rainfall, and a large map showing the distribution of the recording stations.

BULLETIN No. 13 of the Madras Fisheries Department (1922) contains the Reports on Administration for the years 1919–20. The publication is, however, a notable one in that it also contains a long report (pp. 35 to 266) by Sir Frederick Nicholson on methods of fish canning, preparation of oils, guano, etc., with special reference to local methods. There is also an interesting account of the "solar oven," a contrivance for entrapping the heat of the sun in a confined atmosphere. With an outside temperature of 140° F. that of the inside of the oven reached 325° F.

IN the July issue of the *Antiquaries Journal*, Sir Hercules Read publishes his presidential address delivered on St. George's Day. It is devoted to the question of collaboration in archæological research with foreign nations, in particular with France and the United States. Special attention is paid to the question of an agreement with the Afghan Government which granted to the French through M. Foucher a perpetual monopoly of archæological investigation in Afghanistan. This was a serious invasion of the rights of India to share in the excava-

tion of the important Buddhist sites beyond its north-western frontier. It is satisfactory to learn that the matter has now been amicably arranged. The French Government has also expressed readiness to welcome the collaboration of British investigators, and the existence of the concession will not affect their participation.

A LIST of the new books and new editions added to Lewis's Medical and Scientific Circulating Library during June has just been issued by Messrs. H. K. Lewis and Co., Ltd., 136 Gower Street, W.C. 1. It is sent free upon request.

MESSRS. J. AND A. CHURCHILL announce the early publication of the translation of vol. 2, pt. 2 of Molinari's "Organic Chemistry," completing this section of the work. The new part will deal with the esters, oils and fats, sugars and other carbohydrates, cyclic compounds, dyestuffs, textile fibres, proteins, etc.

UPWARDS of 1600 works in botany, zoology and general natural history, many of which are rare, are included in the latest catalogue (New Series, No. 8) of Messrs. Wheldon and Wesley, Ltd., 2 Arthur Street, W.C.2. They originally belonged respectively to Prof. G. A. Boulger, Mr. F. N. Campbell, Sir F. W. Moore and Sir Edmund Giles Loder, Bart. The list is worthy of perusal.

AMONG the announcements of Messrs. Ernest Benn, Ltd., are "The Art of the Chinese Potter," by A. L. Hetherington and R. L. Hobson, which will illustrate 192 choice examples of pottery dating from the Han Dynasty to the end of the Ming, in a series of coloured and half-tone plates; "The Art History of Ancient Peru," by Drs. W. Lehmann and H. Döring, being the first publication of the Research Department of the Ethnographical Museum, Berlin, and "Introduction to the Study of Chinese Painting," by A. Waley, which will be compiled almost entirely from native texts, few of which have been translated before.

Our Astronomical Column.

D'ARREST'S COMET.—No news of the detection of this comet is yet to hand; this is not altogether surprising, as it has been noted faint at previous returns; and as it has not been seen for two revolutions, the positions given may be somewhat in error. The search is still possible in August; in fact, the maximum brightness is in the last week of August. The following is a continuation of Mr. F. R. Cripps's ephemeris (for midnight):

	R.A. h. m.	Decl.	log r.	log Δ.
July 28.	16 29·6	4° 39′ N.		
Aug. 1.	16 32·8	2 45	0·160	9·837
5.	16 37·1	0 46 N.		
9.	16 42·1	1 17 S.	0·151	9·837
13.	16 47·2	3 24		
17.	16 54·1	5 34	0·143	9·840
21.	17 1·5	7 46 S.		

r, Δ are the distances from sun and earth in astronomical units.

The comet should be looked for about 20° west of south, as soon as the sky is dark.

THE CEPHEID VARIABLES AND THE DISTANCE OF THE CLUSTERS.—These variables were largely used by Prof. Shapley in his deduction of the distances of the globular clusters. In the last two years both Prof. Curtis and the late Prof. Kapteyn have challenged these distances; they suggested values about one-seventh of Shapley's. Kapteyn's result was based on all the available proper motions of the Cepheids; he concluded that these were larger than would be expected on Shapley's formula of their distance. Mr. R. E. Wilson, of Dudley Observatory, Albany, returns to this question in *Astron. Journ.* No. 821; he uses all Kapteyn's material, together with a considerable amount of new matter, so that his list contains eighty-four stars. He divides them, as others have done, into the short-period cluster type, and those with periods exceeding two days. Mr. Wilson has also collected observations of radial velocity for thirty of these stars, six being of type I. His conclusion is that these short-period variables are rapid movers in space, the indicated velocity being of the order of 100 km./sec. He therefore considers that Kapteyn's distances for these stars, which were based on a much lower assumption of linear speed, are too small. The stars of longer period are presumably more massive, and their peculiar speed is found to be 12 km./sec. Wilson's estimate of the cluster distances is of the same order as Shapley's, but he suggests a reduction of the latter by an amount not exceeding 40 per cent.

Mr. Wilson also uses his results to test Kapteyn's suggestion that Boss's proper motions in declination need systematic correction by the formula $+0{\cdot}013''$ cosine decl. The material is too scanty to give a conclusion, but it suggests that a correction of half the size indicated by Kapteyn is needed.

PHOTOGRAPHY OF METEORS.—The great difficulty in "catching" a meteor on a photographic plate is referred to by Dr. Harlow Shapley in a brief report on a photographic survey for bright meteors (Harvard College Observ. Bull., No. 788). Harvard College possesses a series of plates extending over an interval of twenty-three years. Each plate covers more than twelve hundred square degrees, and the average length of exposure is sixty-nine minutes. These plates show stars to the eleventh photographic magnitude or fainter, and were made with a one-inch Cooke lens of thirteen inches focal length. The most striking result of this systematic examination of 641 direct photographs is the infrequency of meteor trails. Four sets of regions and time intervals were so chosen that each included the radiant point and the date of a well-recognised meteor shown, and the total exposure time for all these plates amounted to 44,266 minutes. Thus, as is stated, the present survey is equivalent to a photographic search for bright meteors for 738 hours over a region with a diameter of nearly forty degrees, and yet only twelve meteors were recorded. The results are briefly summarised as follows:

	No. of Plates.	Total Exposure min.	Meteor Trails.
Perseids . . .	95	6,379	3
Orionids . . .	93	6,250	0
Leonids . . .	143	9,528	1
Andromedids .	310	22,154	8

ERRATUM.—Meteor of July 11, p. 110, last line. For "15° W. of south" read "15° E. of south."

Research Items.

THE SCOTTISH TABOO OF PORK.—In the memoirs of the Manchester Literary and Philosophical Society (vol. 661), Mr. Donald A. Mackenzie investigates the Scottish objection to the use of pork. He remarks that while the Celts, the medieval clergy, Angles, Saxons, Vikings, and Flemings settled in Scotland reared swine and ate their flesh, the prejudice against this meat was perpetuated by the descendants of the indigenous races, the common folk. The prejudice in the Hebrides has been acquired from them, and James VI. of Scotland and some contemporary lords likewise succumbed to the taboo. Mr. Mackenzie doubtfully traces the belief to Egypt, where Set, the slayer of Osiris, "was the prototype of the Satanic pig demon," and the cult of the pig was associated with that of the Great Mother.

PRIMITIVE STONE WEAPONS FROM UGANDA.—In the publication of the Geological Survey of Uganda (Occasional Paper No. 1) Mr. R. A. Smith of the British Museum and Mr. E. J. Wayland, director of the Geological Survey, Uganda, describes a collection of stone implements made in that province. A report on some of the implements, resembling the rostro-carinate type from below the Suffolk crag, has been already published by Mr. Reid Moir (NATURE, July 21, 1921, p. 649). As only a selection of those implements has come to Europe, Mr. Smith believes that "it would be premature to use these types as evidence of date, in reliance on parallel forms elsewhere; but the palæolithic character of thousands of flints from Egypt is now generally admitted, and the publication of a new series from Uganda may throw light on the Stone Age of Africa in general."

RUGBY AND HOCKEY IN ANCIENT GREECE.—In the April issue of *Discovery*, Mr. Stanley Casson directs attention to one of the most remarkable finds of Greek sculpture in the city wall of Atticus, near the so-called Theseium. These have been already published in the *Journal of Hellenic Studies* for 1922. In one of the reliefs, the players are grouped round an imaginary central line which divides the relief into two equal parts. The six players thus form two teams of three. The foremost on each side is moving at a moderate pace, the central figures at a faster pace, and the figures at the back of each team at a slow pace, almost a walk. To use modern Rugby terms, they might be called "forwards," "three-quarter-backs," and "full-backs." The team that appears to be advancing has possession of the ball, which is a small one, and is held in the hand of the "full-back." Mr. Casson goes on to show that four games of ball, one the Athenian form of Rugby, are described in the "Onomasticon" of Julius Pollux dedicated to the Emperor Commodus, about A.D. 177, which may be described as a "young man's guide to University life." The relief depicting the Athenian equivalent of hockey is of equal interest.

ANATOMY OF THE SHIELD-URCHINS.—Prof. Koehler of Lyons has taken the opportunity presented by his account of the Echinoidea in the Indian Museum (Calcutta, 1922) to study, so far as the state of the material permitted, the internal anatomy, particularly that of the gut, in the Clypeastroida or shield-urchins. He has discovered a composite gland, lying along the front part of the ventral coil of the intestine, and presumably pouring into it some digestive secretion. This intestinal gland was found in all those of the Clypeastroids examined that had the auricles for the attachment of the jaw-muscles separate, but not in those where the auricles were fused into inter-radial processes. The classification based on that skeletal feature thus receives confirmation; but the correlation is no doubt primarily physiological. The arrangement of the intestinal siphon (or by-pass) is also found by Prof. Koehler to vary according to the families already recognised. The relation of the internal calcareous pillars of the Clypeastroids to the soft parts is patent: it can be detected even in the fossils. Prof. Koehler has therefore little difficulty in showing the importance of this so-called "endoskeleton" for classification. The only difficulty that might arise, namely, the reluctance to break open a rare specimen, is, as his excellent photographs prove, easily overcome by radiography. This important memoir on recent sea-urchins will thus strengthen the student of their fossil relatives in his conviction that he is proceeding on safe lines when he bases his genealogies on minute differences of skeletal structure.

MYXOSPORIDIA PARASITIC UPON JAPANESE FLAT FISHES.—In the Journal of the College of Agriculture, Hokkaido Imperial University, Sapporo, Japan, T. Fujita shows that the flat fish of Hokkaido are more highly susceptible to the infection of myxosporidian parasites than the allied forms in the North Sea, the infecting ratio of the parasites being 94 per cent. in the species of the hosts, and 68 per cent. in 453 fishes examined. Observations were made on the gall bladder, this being the most favoured site of the parasites. The species of parasites found are of three genera and eleven species—three of Leptotheca and four of Ceratomyxa and of Myxidium. All are new species. Usually only one was found in a species of the host, though Myxidium was found existing with Ceratomyxa or Leptotheca; the two latter rarely associated together. Ceratomyxa gives the greatest infection and predominates on the east coast. The other genera named are found mostly on the west coast. There appears to be some relation between the occurrence of the parasites and the geographical position of the locality from where the fish are taken. There is an increase in frequency the farther south the fish are found. The author concludes that some parasites seem to prefer a certain depth as their proper abode, Leptotheca attacking mainly the fish in shallow seas while Ceratomyxa abounds mostly in deeper waters.

BARK CANKER OF APPLE TREES.—Part IV. of volume 8 of the Transactions of the British Mycological Society contains a paper of considerable economic interest by Grace G. Gilchrist upon bark canker disease of apple trees. This disease, due to the fungus *Myxosporium corticolum* Edgert., produces large longitudinal scars upon the branches. It has been described by American workers, who regard the damage it produces as negligible. Miss Gilchrist points out that the two outbreaks recorded for England both show severe damage produced as a result, the wood as well as the cortex of the trees being affected.

THE STRUCTURE OF THE PLANT CELL WALL.—The Journal of the Textile Institute, vol. 14, No. 4, April 1923, contains a long paper by H. J. Denham upon the structure of the cotton hair, which deals with the problem of the formation of the plant cell wall. Recent papers by Dr. W. L. Balls have suggested that the thickening of the wall follows by regular deposition of cellulose upon a plan predetermined by the structure of the primary wall which is deposited during the period of extension in length of the hair. Mr. Denham seems unable to agree with this view, as he finds that the striation

patterns of the secondary layers may differ from each other and from that of the primary wall upon which they are deposited. This difference in point of view should promote the advance of our knowledge of the wall structure, and certainly both these workers have materially added to our technique in this difficult field. One may cite, for example, the photographic illustration in the present paper of the growth-rings first demonstrated by Dr. Balls and of other wall structures, such as pits and spirals. Mr. Denham illustrates and discusses at some length the various abnormalities in cell-wall structure met with by several workers, and shows that considerable importance may attach in this connexion to the development of the hairs crowded and compressed within the boll. Based partly upon the study of the staminal hair of Tradescantia, the very interesting suggestion is made that the spiral striation in the cell wall may follow from its deposition along the track of the spirally rotating cytoplasm. Such a spirally rotating band of cytoplasm will of necessity travel in two streams, lying side by side but moving in opposite directions, and the deposition of particles from such a moving band would be expected to vary from the centre of the band to the margin. Here the author finds a possible explanation of the double spiral line of weakness which he demonstrates in the wall of the hair and regards as the cause of the convolutions which are so important to the spinner.

THE DIAMOND-PIPES OF ARKANSAS.—The first diamonds from Arkansas were picked up near Murfreesboro in 1906, on the surface of a pipe of peridotite that had been correctly appreciated by J. C. Branner seventeen years before. Abundant small stones are now extracted from surface-diggings in the decomposed peridotite or peridotite-tuff that fills exploded vents, and the associated strata clearly show that the intrusions occurred at the opening of Upper Cretaceous times. The question as to whether the diamonds were generated in the ultrabasic magma, or whether they have been brought up from some mass through which the invader broke, cannot be regarded as settled; but the list of their associates, including garnet and diopside, seems to indicate the presence of eclogitic rocks in the depths. The occurrences have now been described by H. D. Miser and C. S. Ross in Bulletin 735-I of the U.S. Geological Survey (1923). The largest diamond so far recorded from Arkansas weighs 20·25 carats, which comes within the limits of what may be regarded as a large stone. The age of the pipes is of interest in connexion with what is now known as to the S. African examples.

THE CARBONIFEROUS FLORA OF GREAT BRITAIN.—Under the auspices of the Geological Survey, Dr. Robert Kidston is bringing together the results of his long and happily continuing work on British Carboniferous plants. It is proposed to issue some ten quarto parts as Volume II. of the palæontological memoirs of the Survey, including critical descriptions and illustrations of every known species in the flora. The first two of these parts are now ready (1923), price 15*s.* and 12*s.* 6*d.* respectively. There is nothing on the covers to indicate to the purchaser that he is not receiving the whole work on the "Fossil Plants of the Carboniferous Rocks of Great Britain" in the limits of one part, and the separate sheet issued with Part 2 would lead him to conclude that he was dealing with the second part of the second volume of the book. The final title-page will set this right for our librarians. So far, all the species retained in the "form genus" Sphenopteris have been dealt with; but it is suggested that some may in the future be removed from the ferns to the pteridosperms as their mode of fructification becomes known. The photographic plates, by the Zinc Collotype Co. of Edinburgh, are admirable in the lighting of the specimens. Dr. Kidston's broad outlook makes the memoir a noble contribution, not only to palæontology, but to stratigraphy. On the latter point we may note that the author adopts "Westphalian," but not "Viséan," "Tournaisian," or our own broad "Aronian," and that the "Millstone Grit" horizons become divided (p. 14) between a "Lanarkian" series in the Upper Carboniferous and the highest beds of the Limestone series in the Lower Carboniferous sub-system.

THE SALTS OF THE DEAD SEA AND RIVER JORDAN.—In the *Geographical Journal* for June Mr. W. Irwin has a paper on this subject. Analyses of samples of Dead Sea water show considerable variation according to the spot from which the sample is taken, but the total solids do not vary greatly. The outstanding change is a decrease of sodium salts and an increase of magnesium salts on passing from the north to the south, and to the deepest part of the centre of the lake. This alteration can be caused only by the sodium salts crystallising out on the bottom, leaving the more soluble magnesium salts in solution. Tests of Jordan water show a surprising salinity, averaging, at Jericho, 0·0364 gm. chlorine per 100 c.c. Further analyses in different stretches of the river gave interesting results. As near its source as the Waters of Merom it is highly impregnated with salts, chiefly chlorides of sodium and magnesium, and the composition of the water does not change as far as the Sea of Galilee. In the Sea of Galilee there is a slight increase in these chlorides and a decrease in calcium sulphate and silica, due no doubt to evaporation on one hand and precipitation on the other. By the time the river reaches Jericho there is an increase of salts, especially magnesium chloride. The result of these investigations is to suggest that the principal origin of the salt in the Dead Sea is from the Jordan, which brings it from Hermon and possibly Lebanon. Assuming the bulk of magnesium chloride to be provided by the Jordan, the present level of the Dead Sea must be rising at the rate of 1 ft. in 125 years, for the Jordan brings in 181 million pounds a year, and if the solution is already concentrated and none crystallises out, as appears to be the case, an annual additional depth of water estimated to be 1/125 ft. is required.

WEST INDIAN EARTHQUAKES.—Prof. S. Taber has recently published an interesting study of the seismic belt in the Greater Antilles (Bull. Seis. Soc. America, vol. 12, 1922, pp. 199-219). In this region, the major relief features are zones of normal faulting developed in late geological times, and still, as the occurrence of earthquakes shows, being developed. The two most persistent fault-zones are the Swan Island–Jamaica–South Haiti and the Cayman Islands–Sierra Maestra–North Haiti, which are roughly parallel for a distance of nearly 2000 km. and are only 100 to 150 km. apart. The narrow strip between these fault-zones is depressed in its western and central portions so as to form the Bartlett trough (3506 fathoms). With few exceptions, all strong Antillean earthquakes have originated along a few well-defined belts which coincide with the major fault-zones of the region. There is no evidence either of a continuous change in the seismicity of the region or of any well-defined periodic variation. When severe earthquakes have been separated by a short time-interval, their epicentres have been in the same fault-zone and only a short distance apart, thus indicating that the displacement was being

extended along the strike of the faults. Most of the great earthquakes originating along the shores of the islands have been accompanied by sea-waves, each of which, so far as known, has been propagated with the trough in advance of the crest. The wave thus seems to indicate a sudden downward displacement of the ocean-bed. Disastrous earthquakes seldom recur in exactly the same place except after long intervals. Thus, those parts of the zones of active faulting near which severe earthquakes have not occurred in historic times are to be regarded as seismically the most dangerous.

VOLUMETRIC DETERMINATION OF RAINFALL.—A paper on this subject by Mr. C. S. Salter was read before the Inland Navigation section of the thirteenth International Congress of Navigation held recently in London, and is published as a pamphlet. The sources of error in rainfall records are three: design of rain-gauge, exposure of rain-gauge, and interpretation of records in terms of volume. Mr. Salter's paper deals with the last consideration. Owing to the fact that rainfall is extremely variable in its incidence in time and its distribution in space, the reading of an individual rain-gauge must be regarded as merely a sample. The total rainfall of an individual month in Britain may vary by 400 per cent. from the average value, and that of an individual year by 70 per cent. When the period of records is short no allowance for the variation of time is possible, but a correction can often be applied from adjacent long records. Generally speaking, in rainy districts, where thunderstorms and sporadic rains do not bulk largely in the total fall, from one to two years give a sufficiently good basis for a factor of correction to be applied with safety, provided that a long record is available at no greater distance than five to ten miles. In districts where the total fall is so small that a single thunderstorm may introduce great local variations, from four to five years' records are necessary. Variations in space are relatively easily applied with the help of an orographical map. A rainfall map is the best medium for computing the volume of rainfall over a gathering-ground as a whole, and the best and simplest method is by planimeter measurement.

THE WINDS OF HONGKONG.—A discussion under the direction of Mr. T. F. Claxton "to ascertain the difference in direction and velocity of the wind at the Royal Observatory, Kowloon, and at Victoria Peak, Hongkong, at different seasons of the year and at different hours of the day," has been issued by the Royal Observatory, Hongkong. The results are based on the records of Beckley anemographs for the period 1914-1918. The Royal Observatory is situated on a hillock, 100 feet high, about 1000 yards from the harbour; the surrounding country is flat, except to the north. Victoria Peak is 1840 feet above sea-level and is situated 3 miles to the south-west of the Royal Observatory. To the north, west, and south, the sides of the Peak are very steep, and the easterly winds are affected by the Hongkong hills. The anemograph records at the Observatory are measured at the half hours, and the value set against any hour is the run of the wind from 30 minutes before to 30 minutes after that hour. At Victoria Peak the records are measured at the hour, and the value set against any hour is the run of the wind since the previous hour. This difference in the method of registration seems likely to affect the results for comparison. Detailed hourly observations of direction and velocity are given for the two exposures for the years 1914–1918. The different situations naturally give different results, which are shown by numerous tables and diagrams. For normal wind results, for comparison with other world observatories, the results at Victoria Peak should probably be preferred, although both situations seem to leave much to be desired.

IONIC DISSOCIATION IN SOLUTION.—P. Debye and E. Hueckel have investigated the electrostatic forces between the ions of the solute, and the dipole action of the molecules of the solvent (*Phys. Zeits.*, May 1). They assume that the whole of the dissolved salt is dissociated; and for dilute solutions arrive at the equation

$$\theta = w\frac{\epsilon^2}{6\mathrm{D}k\mathrm{T}}\sqrt{\frac{4\pi\epsilon^2}{\mathrm{D}k\mathrm{T}}n\Sigma\nu_i}, \tag{1}$$

where θ, the deviation from the classical theory, $=(\Delta_k - \Delta_i)\Delta_k$, Δ_k being the lowering of the freezing point given by the classical theory and Δ_i that actually observed; w is a valency factor equal to $(\Sigma\nu_i z_i^2/\Sigma\nu_i)^{\frac{3}{2}}$. The dissolved molecule is split up into $\nu_1 - \nu_i - \nu_s$ ions of different kinds $1 - i - s$, with valencies $z_1 - z_i - z_s$, and w is calculated from these values; $\mathrm{T}=273$ when the solvent is water, $\epsilon = 4\cdot77\times10^{-19}$ e.s.u., n is Loschmidt's number $= 6\cdot06\times10^{23}$, $k = 1\cdot346\times10^{16}$ ergs, D, the dielectric constant, is 88·23 for water at 0° C., $\Sigma\nu_i = \nu$ is the number of ions into which a molecule of the salt splits up. Using these values,

$$\theta = 0\cdot270 w\sqrt{\nu\gamma}; \tag{2}$$

and curves have been drawn showing the experimental relation between θ and $\sqrt{\nu\gamma}$ for a number of salts of varying constitution, including magnesium sulphate, lanthanum nitrate, potassium sulphate, and potassium chloride. These curves follow the straight lines obtained by giving w in (2) the proper values, for a considerable distance from the origin. For higher concentrations the deviations from the straight lines depend on the individual properties of the ions; and particularly on their dimensions, which were neglected in deriving (1) and (2). When the dimensions are taken into account, theory is found to agree very satisfactorily with experiment up to much higher concentrations. For very high concentrations other factors, previously neglected, have to be considered; there appears to be no doubt that, even in this case, the molecules of the solute are split into their ions.

STEREOSCOPIC PROJECTION.—Much attention has been directed in recent years towards obtaining a satisfactory method of stereoscopic projection. Many of the devices proposed involve the use by the individual observer of spectacles or binoculars with coloured glasses or interrupting shutters. The Daponte Stereoscopic Projector or "Pulsograph," which was exhibited by Mr. E. Sanger-Shepherd at the Royal Society Conversazione on June 20, employs an entirely different principle, whereby a "stereoscopic" effect can be readily observed by the unaided eye of the spectator. Two photographs are taken from two positions slightly separated, and projected in register on an ordinary screen by two optical systems. Between the source of light and the transparency in each of the optical systems a rotating shutter is placed, consisting of a glass disc with a graduated grey film varying from black at zero to clear at 180° and back to black at 360°. When one shutter is passing maximum light the other is at minimum transmission position, the rotating shutters dissolving the right-hand picture into the left-hand picture and *vice versa*. With the discs at the position of equal transmission, that is at the 90° position, a double-image picture appears, since the two stereoscopic photographs are not exactly alike; but on the discs being rotated the "stereoscopic" relief effect is immediately obtained. The "Pulsograph" can be employed for the projection of lantern slides, solid objects, or of kinematograph films.

Problems of Fundamental Astronomy.[1]

By Prof. W. DE SITTER, University of Leyden.

THE science of astronomy has, in the past twenty or thirty years, developed most remarkably. The marvellous applications of photography and spectroscopy on one hand, and the sudden growth of statistical stellar astronomy consequent upon the discovery of the two star-streams on the other, have led to so many unforeseen results and so many new points of view, that it almost appears as if the whole science were born anew and the astronomy of to-day had only very slight connexions with that of the last century: we are apt to think that the great problems of the past have lost all their interest to us. This, however, is not so. On the contrary, I think the central problems of fundamental astronomy have gained an enhanced importance even by the newest developments of the science.

Astronomy is essentially the science of space and time. It is not my intention, in thus assigning to astronomy this wide field, to annex to it the whole of physical science. On the contrary, I am quite content to consider astronomy only as a special branch of physics, but, having at its disposal the largest spaces and the longest times, it has generally had the last word in all important questions. To mention only a few cases at random: the discovery of gravitation, of the finite velocity of light, and of aberration, all these are astronomical discoveries, and the three crucial tests of Einstein's theory are all three astronomical.

In our exploration of space and time we are compelled to make all our measures from this earth, to which we are tied, as a starting-point. The problems of fundamental astronomy are those which arise from this fact, that all our observations are necessarily referred to a moving origin. These problems are, from their nature, not very liable to change of aspect with time or fashion; they are essentially the same to-day as they were in the time of Hipparchus, the founder of astronomy, and they will remain the same so long as science lasts, and will require ever more accurate and more complete solutions, as we penetrate more deeply into the constitution of the universe. Fundamental astronomy thus consists essentially of a scrutiny of the last decimal place. This striving after extreme accuracy, this fidgeting over small quantities, may appear uninteresting, or even pedantic. But we must not forget that great problems always turn about the measurement of small quantities.

The problems of fundamental astronomy are, of course, all interconnected with each other, but, for the sake of clearness, they may be classified under three heads. There are, first, the problems connected with the system of constants. The motion of the earth, and the system of measurement based on it, are defined by several numbers, such as the solar parallax, the constants of precession and nutation, the ellipticity, the mean radius and the mass of the earth, etc. Between these several constants there exist relations, connecting two or more of them with each other and with other universal constants such as the velocity of light and the constant of gravitation. The problem here is essentially one of adjustment, so as to get a consistent set of constants satisfying all the connecting relations. The set of constants in actual use in the national ephemerides is not consistent. The discordances are, however, not very large, and changes should not be introduced unless by general international agreement.

Another set of problems are those connected with the rotation of the earth. The paramount practical value of this rotation is that it is used as our standard measure of time.

Time is measured by observing the changes occurring in some physical system—*i.e.* in the relative positions of some material bodies, which positions at any time are determined by our theories, so that from the observed positions we can infer the time. Such a mechanism—by preference periodic—that is used to measure time may conveniently be called a "clock." But there is no absolute measure of time, nor an absolute test of the accuracy of any clock; we can only test one clock by another. If the two do not give the same time, then one or both must be wrong, *i.e.* our theories of the mechanism of one or both must be incomplete. The standard clock to which all others are generally referred is the rotating earth. Is this standard absolutely trustworthy? Do all observatories give the same time, and if so, is this a truly uniform time? In other words: does the earth rotate as a rigid body, and if so, is this rotation strictly uniform?

It has long been suspected that the earth's rotation is very gradually slowing down, owing to the friction of the tidal wave.[2] But lately other doubts have arisen as to the trustworthiness of our universal standard. As a matter of fact, it is not the rotation of the earth, but the rotation of a definite point on the earth—Greenwich Observatory or any other observatory—that is used as our standard, and now that the wireless distribution of time signals has made comparisons so easy, occasional discrepancies between the times of different observatories, amounting sometimes to several tenths of a second, have come to light.[3]

It appears probable that these are due to errors in one or more of the parts of the mechanism used to determine the time at some or all of the observatories—the transit instruments, the clocks, the astronomers—but it also may be that they are due to real differences in the rotation of the different observatories, which would mean that the earth does not rotate as a rigid body, but some parts of its surface are moving relatively to other parts.[4] Here evidently is a most important problem, the solution of which must be found sooner or later.

Besides the rotating earth, we have other "clocks," of which the moon must be mentioned in the first place. It is well known that in the motion of the moon there are irregularities of a much longer period, called "fluctuations" by Newcomb, for which no explanation has yet been found. Brown[5] and Glauert[6] have pointed out similar irregularities in the motions of the sun, Venus, and Mercury. If this were confirmed, and if also other bodies—especially Jupiter's satellites—should show the same thing, then it would become very probable that the true origin of these fluctuations is in the rotation of the earth, or at least of the outer crust of the earth.

Other problems connected with the rotation of the earth, and the question whether it rotates as a rigid body, are those involved in the variation of latitude.

[1] Synopsis of a lecture delivered at the Imperial College of Science and Technology, South Kensington, on May 7.

[2] Taylor, Mon. Not. R.A.S. lxxx. 308; Jeffreys, *ibid.* 309.

[3] Sampson, Mon. Not. R.A.S. lxxxii. 215; Dyson and Bowyer, *ibid.* lxxxii. 193.

[4] Dr. Innes (Johannesburg Circular 55) has recently directed attention to irregularities in the moon's motion of the same character as the discordances between the times of different observatories referred to above. But these are derived from several observatories, giving concurrent results, so that it would appear that the error is in the moon, and not in the time.

[6] Mon. Not. R.A.S. lxxv. 489.

There seems to be evidence[7] of sudden as well as slow and continuous changes, which, if they are real, may be due either to shifting of parts of the crust of the earth relatively to each other, or to a slow sliding of the whole of the crust over the core.

All these problems, which evidently are of the greatest importance not for astronomy alone, depend for their solution on very small quantities which even now only begin to come within the reach of our most accurate measures and most refined discussions.

The third set of problems of fundamental astronomy concern questions relating to the positions and motions of the fixed stars. Bessel's great work called "Fundamenta astronomiae" consists of a careful discussion and synthesis of the observations made by James Bradley as Astronomer Royal at Greenwich upon the positions of the stars.

Indeed, the positions and motions of the "fixed" stars are the basis on which the whole structure of astronomy rests. The manner in which these positions are determined is forced upon us by our location on the moving earth. The accumulated labours of astronomers since the commencement of accurate observing by Bradley have resulted in a system (or rather three systems, differing by small, but not negligible, quantities) of positions and motions of the stars. These are referred to a frame of reference, which is defined by the motion of the earth, and consisting of the equator, and a zero point on it. Both the equator and the zero point are moving. It need scarcely be stated that the formation of such a system of positions and motions of stars is a most intricate and difficult problem, and we must confess that it has not, so far, been solved in a manner which satisfies the demands of statistical astronomy and cosmogony.

The system which is generally considered the best of those now in use, that of Boss, is by no means perfect: large errors in it are not at all improbable.[8] These errors are errors of the system, not of the individual star-positions, and the question naturally arises: Is an "absolute" system at all necessary? Strictly absolute, of course, it is not: all systems of reference are relative. By "absolute" we mean relative to the inertial frame defined by the motion of the earth in the solar system. But is it necessary to base our system of star-positions on this motion of the earth? Would it not be much more natural, and much more simple as well, to have relative positions and motions of the stars with regard to one another, or to the general average of them?

Many astronomers are inclined to answer this question in the affirmative, and to consider the absolute system more as a time-honoured institution of our predecessors, a venerable relic from the pre-photographic days, than as a useful and necessary adjunct of modern stellar astronomy. In fact, by the application of photography, we can easily derive relative motions, or motions of individual stars relatively to the "background," with an accuracy which many times exceeds that attainable by fundamental methods.

By the blink-microscope we find, with comparatively very small labour, proper motions of very satisfactory accuracy referred to the background of faint stars in the area examined. Of course this "background" is a rather loosely defined frame of reference, and we have no guarantee that the motions of stars in different areas of the sky are really referred to the same frame. A more elaborate method of referring the relative motions determined photographically to a quasi-absolute system is proposed by Kapteyn.[9] This method, however, depends on the hypothesis that the sun's motion relative to faint stars is the same as that relative to bright stars. This is why I call it a "quasi-absolute" system. Are not the proper motions derived by these and similar methods quite as valuable as those found by fundamental methods?

My answer is decidedly in the negative. We cannot do without the "absolute" system of fundamental astronomy. The value of that system is not that it is attached to the earth, but that we know exactly what the frame of reference is and that it is a rigorous system, giving certainty that all motions are really referred to the *same* frame. To see the importance of this, I will put some questions, which cannot be answered until we have a fundamental system including the faint stars.

Is star-streaming a universal phenomenon, or is it local, and in the latter case, how far from the sun does it extend? Do the Orion-stars take part in the star-streaming or not? Is there a systematic motion of faint stars relatively to bright stars; or in other words, is the average motion in space of the stars independent of their brightness?[10] Is there a rotation of the system of stars as a whole?

These and similar questions are again examples of great problems the solution of which depends on very small quantities. These small quantities, the proper motions of faint stars, cannot be profitably discussed unless we have the certainty that these motions are referred to a rigorous system.

The necessity of a fundamental system being granted, we must next ask: how are we to improve and extend our present system? Must we, in order to establish an absolute system, necessarily retain the old methods, or can we find other means? Is the meridian instrument to remain the only one by which star places are to be determined? To this question I wish, as emphatically as to the former one, to answer in the negative. We must look for other methods, if it be only to verify the results from the meridian work.

Here I think is the greatest problem, and the most urgent problem, of fundamental astronomy. It is twofold: the determination of the positions of the stars, and that of their motions. We must thus not only establish a rigorous and faultless system of star positions for the present day, but also strengthen as much as possible our knowledge of the positions in the past. These latter as now used depend practically exclusively on Bradley's observations. But there are other data available, though not yet, or not yet sufficiently, reduced. Among these the most important are the rich mine of material still lying unused in the observations made in the last quarter of the eighteenth century and the first quarter of the nineteenth by Hornsby and Robertson at Oxford.[11] I think the careful reduction of these observations, which are of the same excellent quality as those of Bradley, is one of the most urgent demands of fundamental astronomy.

As to the means by which the modern positions must be determined, I will not attempt now to enter into details regarding the methods which have been, or may be, proposed to supplement the classical meridian methods. All I wish is to convey an idea of the meaning and the importance of the problems of fundamental astronomy, and to show that far from being uninteresting remains of a past period, their solution has become even more urgent by the newest developments of several branches of modern astronomy.

Night Temperature on Mt. Etna.

THE observatory on Mt. Etna is perched high up on a plateau of the volcano known as the Piano del Lago beneath the summit ridge, which rises about 1000 feet higher. It is sometimes noticed by the officials, who only reside a few days in each month, that a curious rise in temperature, amounting to a couple of degrees or so centigrade, occurs during the middle of the night, constituting a well-marked secondary nocturnal maximum in the diurnal variation of temperature. During a visit to the station in August 1920, Prof. Filippo Eredia noticed that the nocturnal inversion in the regular fall of temperature was associated with the arrival of sulphurous fumes from the crater, but notwithstanding the contemporaneous occurrence he does not attribute much causal connexion between the two phenomena. A dozen cases, as shown by thermograph records, are discussed by him in a paper contributed to vol. 31 (1922) of the Rendiconti della Reale Accademia Nazionale dei Lincei. Most of them occurred in the summer, and in conditions both of calm and of wind of different forces and directions, chiefly N.E. and N.W. The calm cases with clear sky are shown to be analogous to similar nocturnal inversions in other mountain regions, and are attributed partly to the slow descent of air from the summit ridge whereby it is warmed by adiabatic compression, and partly to the latent heat of misty condensation due to the previous general nocturnal chilling of the atmosphere. This, however, is not quite convincing; the effects are too complex to be explained on a purely qualitative basis. The cases with strong wind are found to be associated with a great difference of temperature between the interior of Sicily and the eastern flanks of Etna, giving rise to a circulation which carries warmer air to the high-level station. At Catania on the coast near sea-level there are no corresponding night inversions of the diurnal range of temperature.

Although the above are only examples of secondary night maxima, the inversion of the regular variation not being nearly marked enough to override the primary day maximum in 24 hours, it is probable that in the latitude of Sicily, where the range of temperature between day and night is at all seasons large, such minor irregularities in the diurnal course of temperature attract more attention than they would in a higher latitude, where during the very short days of winter the diurnal range is small and liable to be obliterated, or even occasionally entirely inverted, by the very rapid and conspicuous irregular variations of temperature. In England, for example, during the month of December it is no very rare event for night to be warmer than day: for should frosty air begin towards evening to be replaced by a warm, humid current from the Atlantic, not only will the frost be swept away, instead of intensified, as night comes on, but the thermometer may easily rise to 50° F. or above in the middle of the night.

The School of Hygiene in London.

AN inquiry at the Ministry of Health relating to the proposed School of Hygiene in London has elicited the following statement of the position of the scheme.

In May 1921 the committee on Post-Graduate Medical Education, under the chairmanship of the Earl of Athlone, published its report, recommending, *inter alia*, the establishment of an Institute of Medicine in association with the University of London, in which instruction should be given in public health and other departments of medicine. This suggestion was further explored by a small Departmental Committee and detailed proposals were formulated.

The University of London and the Government were, however, unable to find the money to establish an Institute of Medicine such as Lord Athlone's Committee had contemplated, and in these circumstances the proposals were brought to the notice of the trustees of the Rockefeller Foundation, whose representatives had recently been in consultation with the authorities in Great Britain. The trustees of the Foundation generously agreed to provide two million dollars for the establishment of the Institute, to be called the School of Hygiene, the British Government undertaking to make an annual grant towards the upkeep of the School. Preliminary work was undertaken for the preparation of plans and estimates, and a site has been selected.

It has been decided that the School when established shall be affiliated with the University of London but managed by a separate governing body, for which a charter of incorporation will be sought. Pending the presentation of a petition for the charter, the Minister of Health, with the concurrence of the trustees of the Rockefeller Foundation, has appointed a transitional executive committee. The functions of the committee will be to appoint a director, to arrange for amalgamation or co-ordination between the School and other institutions working in similar or closely related spheres, to prepare plans for the new School, and to begin building, unless in the meantime it has been possible to set up the permanent governing body. The members of the committee are: The Rt. Hon. Neville Chamberlain (chairman), the Rt. Hon. the Viscount Burnham, Capt. Sir Arthur Clarke, Sir Walter Fletcher, Lieut.-Col. Fremantle, Sir Harry Goschen, Sir George Newman, Sir Cooper Perry, and Sir Arthur Robinson, with Mr. L. G. Brock, of the Ministry of Health, as secretary.

University and Educational Intelligence.

ABERDEEN.—At the Summer Graduation on July 11, the honorary degree of LL.D. was conferred on Prof. J. Fraser, Jesus professor of Celtic in the University of Oxford.

Mr. William Thomas received the degree of Ph.D. for theses on (*a*) The influence of colloids on reactions involving gases, and (*b*) Inorganic complex salts.

The following prizes were awarded: Collie prize in botany and Sutherland gold medal in forestry to Mr. J. H. Hunter; Struthers medal and prize in anatomy to Mr. J. W. Foster; Lizars medal in anatomy to Mr. J. W. Foster and Mr. A. J. W. Wilkins; John Murray medal and scholarship in medicine to Mr. A. Lyall.

The University Court has decided to make first appointments, in the coming autumn, to the newly founded chair in engineering and to the Cruickshank lectureship in astronomy and meteorology.

CAMBRIDGE.—Mr. D. C. Carroll, Trinity Hall, has been elected to the Michael Foster research studentship; Dr. C. C. Worster-Drought, Downing College, has been elected to the E. G. Fearnsides research scholarship.

LONDON.—At a meeting of the Senate held on July 18, the title of reader in organic chemistry was conferred on Dr. O. L. Brady, of University College;

and the title of emeritus professor on Prof. W. D. Halliburton, on his retirement from the chair of physiology at King's College, which he has held since 1890.

The degree of D.Sc. (*Chemistry*) was conferred on Mr. Jnanendranath Mukhopadhyay (University College) for a thesis entitled "The Adsorption of Ions and the Precipitation of Suspensoids by Electrolytes."

ST. ANDREWS.—The Senatus Academicus will, on the occasion of the installation of Mr. Rudyard Kipling as rector of the University, on October 10, confer the honorary degree of LL.D. on Sir James G. Frazer, author of the "Golden Bough," and on Sir John Bland-Sutton.

Twenty-five years ago the Medical School of the University was re-organised, and Dr. A. M. Stalker was appointed the first professor of medicine under the new conditions. The successful development of the School owes much to Prof. Stalker's great abilities, to his personality, and to his veneration for the University of his adoption. Prof. Stalker having intimated his resignation of the chair of medicine, the Senatus Academicus recorded a special minute expressing appreciation of his loyal service.

The University Court has decided to proceed with a scheme for building additional storeys to the existing teaching laboratories for physics and chemistry and connecting the two by a central building.

THE University of Wales has conferred the honorary degree of D.Sc. upon Sir Charles Sherrington.

THE following awards tenable at the Imperial College of Science and Technology, South Kensington, during the year 1923–24 have been made:—By the governing body of the College: (*a*) The Henry George Plimmer Fellowship in Pathology to Mr. H. R. Hewer, for research on "The Rôle of Stimuli received by the Eye in the Colour Changes of Amphibia and Nerve Supply of the Pituitary," value about 300*l.*; and (*b*) The Gas Light and Coke Company's Research Fellowship, just established by the Company for the purpose of encouraging experimental research in relation to carbonisation, gaseous fuels and combustion, to Mr. F. R. Weston, for "The Spectroscopic Investigation of the Flames of Carbon Monoxide and Hydrogen and matters cognate thereto," value 175*l.*, together with an allowance towards the expense of the research. By the Trustees of the Beit Fellowships for Scientific Research: Research fellowships to Mr. H. W. Buston, for a continuation of his work on the "Nitrogenous Metabolism in Plants," and to Mr. O. M. B. Bulman, for research on "Stratigraphical Geology: The Fauna of the Shineton Shales," value 250*l.* per annum each.

THE coming of age of the Manchester Municipal College of Technology was celebrated on July 5 and 6 by a soirée each evening in the College buildings. The guests were received on the first evening by Viscount Burnham, the Lord Mayor of Manchester, and Alderman West. After the reception Viscount Burnham addressed the gathering and congratulated the city of Manchester on having an institution which, while forming a Faculty of the University, was in touch also with the industries of the district. He spoke of the constantly increasing need for the application of science to industry, and of the importance of selecting appropriate occupations for young people starting work. He saw in the College an efficient instrument for achieving these purposes. Among other distinguished people, Viscount Burnham was supported by the Vice-Chancellor of the University, Mr. Mouat Jones, principal of the College, and Mr. J. H. Reynolds, who was the first principal of the College. The guests were each presented with an illustrated pamphlet, "An Historical Account of the Origin and Development of the Municipal College of Technology, Manchester," written by Mr. Reynolds. The whole of this striking souvenir was produced in the Printing and Photographic Technology Department of the College.

As a mark of appreciation of Sir Michael Sadler's stimulating work for the University of Leeds during the twelve years in which he has held the office of Vice-Chancellor, it has been decided to establish a memorial in the University in the form of his portrait and a fund for assisting necessitous students. Subscriptions—restricted to 5*l.* in an individual gift—are invited for these purposes. In Yorkshire, and to past and present members of the University, the results of Sir Michael Sadler's devoted work for the development of the University are richly manifest, and the response to the appeal is sure to be ready and generous. There are in addition many who hold Sir Michael in the highest esteem, on account not only of his labours as Vice-Chancellor but also for his untiring activities on behalf of educational freedom and growth in institutions of all grades. He has been the uncrowned leader of education in England—indeed, in the Empire—for a generation, and the opportunity of expressing regard for what he has done will be widely welcomed. Contributions should be made payable to the Treasurer of the Sadler Fund and sent to the University, Leeds.

THE Universities of Oxford and Cambridge Bill to give effect to recommendations in the report of the Royal Commission of 1919–22 was read a third time in the House of Commons on Friday, July 20. The Bill provides that there shall be two bodies of Commissioners, one for each University, and directs them to make statutes and regulations in general accordance with the recommendations of the Royal Commission, but with such modifications as may appear expedient. The Universities are given the power independently of the colleges to prescribe what contribution should be made by the colleges for university purposes. The provisions of the Act of 1877 are modified, so that trusts less than sixty years old can be altered with the consent of the trustees. The Marquis of Bath, in moving the second reading, remarked that if it were necessary to reduce the amounts of the grants recommended by the Royal Commission, cuts would have to be made proportionately from the amounts for general purposes, for libraries, for women's colleges, and for extramural boards. On the motion for the third reading, Mr. J. R. M. Butler proposed an amendment amounting to a direct instruction to the Commissioners to take action by giving women full membership at once of the University of Cambridge. It was pointed out by the president of the Board of Education that it made a very considerable difference whether having appointed a number of distinguished men to control the working of a university they resolved that the House of Commons should limit their discretion. The amendment was rejected by 150 votes to 124. An amendment providing that, in making any statutes or regulations, the Commissioners should have regard to the need of facilitating the admission of poorer students to the Universities and colleges, was agreed to. The list of Commissioners includes the names of Sir A. E. Garrod, Sir T. L. Heath, Sir R. T. Glazebrook, and Sir H. K. Anderson.

Societies and Academies.

LONDON.

The Faraday Society, July 2.—Prof. A. W. Porter, past-president, in the chair.—A. **Ferguson**: On a relation between surface tension and density. Macleod has shown empirically that for a number of unassociated liquids, $\gamma = C(\rho_l - \rho_v)^4$, where γ is the surface tension of the liquid at any temperature, $\rho_l - \rho_v$ the difference between the orthobaric densities of the liquid and the vapour at that temperature, and C a constant which is independent of the temperature. This expression is referred to the power law connecting surface tension and temperature first put forward by van der Waals but not generally known, and the Eötvös equation.—U. R. **Evans**: The law of definite proportions in the light of modern research. Many of the series of solid solutions met with in alloys show a maximum *melting-point* (*i.e.* a maximum *thermal stability*) at a composition indicated by a simple atomic formula (*e.g.* AuMg); it is customary to describe this member of the series as an "inter-metallic compound," and to regard it as the parent of the series. But in cases where there is a maximum *hardness* (*i.e.* maximum *mechanical stability*) at a composition indicated by a simple atomic formula (*e.g.* AgAu), or where there is an abrupt change of chemical behaviour (a *parting limit*), it is not at present customary to apply the word "compound.". The fact that the maximum stability usually occurs at a composition expressible by a simple formula is often capable of a physical explanation. Many of the oxides of metals with more than one valency have a variable composition; *e.g.* pure Fe_3O_4 and Fe_2O_3 may be regarded as the "end-members" of a series. Likewise homogeneous bodies of variable oxygen-content occur among the oxides of platinum, iridium, nickel, molybdenum, tungsten, and possibly silver, lead, and thallium. Chlorides of thallium, sub-chlorides and sub-bromides of bismuth, and sulphides of copper, nickel, and cobalt show similar series of homogeneous substances.—J. **Grant** and J. R. **Partington**: Concentration cells in methyl alcohol. The E.M.F. of concentration cells formed from solutions of silver nitrate in methyl and ethyl alcohols as determined by Wilson agrees with that calculated from Nernst's formula only for the latter. Good agreement has been found, however, in both cases.—F. G. **Tryhorn** and S. C. **Blacktin**: The formation of anomalous Liesegang bands. Two examples of the production of anomalous Liesegang bands are cited in addition to the case of lead chromate in agar gels first noticed by Hatschek. The substances formed crystallise from the respective gels more readily in the light than in the dark.—J. B. **Firth**: Determination of the density of charcoal by displacement of liquids. It has been shown that the apparent densities of cocoanut shell charcoal and sugar charcoal have been determined after definite intervals, for several liquids. The values obtained increase with the time of contact between the liquid and the charcoal. Further, the final density value varies with the different liquids. It would appear that the rate of change in the density value and also the final density will be determined by the rate of sorption and sorptive capacity respectively.

EDINBURGH.

Royal Society, June 18.—Prof. F. O. Bower, president, in the chair.—F. **Walker**: The igneous geology of the Dalmeny district. The igneous rocks of the Dalmeny district may be divided into three groups:—(1) Basaltic lavas of Dalmeny type which are of undoubted Lower Carboniferous age. (2) A suite of sills which bear analcite and occasionally some nepheline. These sills are probably to be reckoned as the underground manifestation of Lower Carboniferous volcanic activity. (3) A group of quartz dolerite sills which belong to a later phase of intrusion and appear to be connected with Permo-Carboniferous earth movements. The second group contains some interesting petrographical types including teschenite, camptonite, and theralite. All three types are represented in the Mons Hill sill, which is of great complexity.—Miss Elizabeth **Gilchrist**: The slow oxidation of phosphorus. Phosphorus glows in air but not in oxygen at high pressures; some gases act as poisons while others act as promoters of the glow. The reaction appears to take place in two stages; phosphorus trioxide being produced in the first stage without glowing, and phosphorus pentoxide in the second stage with glowing. The hindering effect is ascribed to the production of an anticatalyst, which probably consists of negatively charged molecules.—G. A. **Carse** and D. **Jack**: On the X-ray corpuscular emission from iron in a magnetised and unmagnetised state. According to Ewing's theory of magnetism there is something in the iron atom that turns in response to an applied magnetic field. Experiments on the X-ray corpuscular emission from iron in a magnetised and unmagnetised state show that in the iron atom either the part that turns does not emit an appreciable number of electrons or the chance of ejection is not affected by the orientation.—Lancelot **Hogben**: The mechanism of amphibian colour response. The pituitary gland of mammals, birds, reptiles, amphibia, and fishes contains a substance which exercises a highly specific effect upon the melanophores of amphibia, inducing a condition of maximal expansion which is not precisely simulated by other drugs or tissue extracts, which agree in their action on plain muscle with pituitrine. The action of pituitary extract on melanophores is local and direct. Like other pituitary antacoids, the melanophore stimulant is destroyed by trypsin. Like the oxytoxic principle, it is more stable to acid hydrolysis than the pressor substance, and is mainly located in the posterior lobe of the fresh mammalian gland. After removal of the pituitary (whole gland) in both adult frogs and larval salamanders, the melanophores remain permanently in a state of maximal contraction, even when the animals are exposed to optimum conditions for producing pallor. When injected with pituitary extracts they expand fully; but the animals regain pallor even under exposure to those conditions which invariably produce melanophore expansion in normal or partially hyopohysectomised animals. The evidence for a direct nervous control of amphibian colour response is inadequate. Pituitary secretion fluctuates in correlation with conditions which evoke pigmentary change.

SHEFFIELD.

Society of Glass Technology (Leeds meeting), June 20.—W. E. S. **Turner**: Specifications in the glass industry. Certain types of glass, such as that used for optical purposes, are bought on specification and must conform strictly to certain properties. In the case of containers for liquids and solids, no attempt is made to manufacture or purchase on the basis of specification. If the glass industry insisted on furnace material makers providing, for example, refractories to specification, then the glass manufacturers themselves should at least show they are prepared to supply their own goods to specification. —Th. **Teisen**: Notes on the design of pot arches. Modern types should contain good facilities for heat distribution and control; they should also combine

good conditions for working and firing with easy installation and economy of space. In one type described, water is kept dripping on the firebars and on a plate arranged in front of them, thereby producing a certain amount of steam; this helps to retard the drying of the surface parts and allows the inside to evaporate its moisture at the same rate as the outside. This type takes up little space with proportionately less building cost, and results in practice are satisfactory.—S. **English**: Notes on the Ashley bottle machine. To one familiar only with modern glass-forming machines, it is surprising to learn that the home of bottle-making machinery is on this side of the Atlantic. The first machine to make narrow-mouth bottles at all satisfactorily was designed and built by H. M. Ashley at Ferrybridge (Yorkshire), about 1886.

PARIS.

Academy of Sciences, July 2.—M. Albin Haller in the chair.—Auguste **Béhal**: The fourth International Congress of Pure and Applied Chemistry. An account of the conference held at Cambridge on June 16-21.—Ch. **Gravier**: The adaptation to tree life of a Madagascan crab.—Henri **Villat**: A singular integral equation and a problem in the theory of vortices.—J. B. **Senderens**: The manufacture of ethyl and methyl ether. A study of the conditions (temperature and strength of sulphuric acid) for maximum yield of these ethers from their respective alcohols. For methyl ether, with sulphuric acid of the strength $H_2SO_4 \cdot 2H_2O$ and at a temperature of 160° C.-165° C., the ether can be made continuously at the rate of 250-300 c.c. per minute.—Bertrand **Gambier**: The curves of Bertrand and the deformation of quadrics.—Richard **Birkeland**: The resolution of algebraic equations by a sum of hypergeometric functions.—J. **Haag**: Certain particular states of a gaseous mass, agreeing with Maxwell's law.—A. **Lafay**: The arborescences traced out by the positive silent discharge.—Félix **Michaud**: The electrical properties of jellies. In an earlier communication the author showed that a jelly, when traversed by an electric current, contracts at the anode and swells at the cathode. From this it follows that a jelly submitted to a pressure gradient should show potential differences. This conclusion is verified experimentally.—F. **Wolfers**: The deviation of the X-rays at the surface of bodies, and the effects produced by a slit.—A. **Lepape** and A. **Dauvillier**: The fine structure of the limits of high-frequency absorption. The L limits of xenon.—M. **Marsat**: A combination of reflectors. An account of an optical arrangement of mirrors for use on motor cars, satisfying the condition that a beam should be cast at least 100 metres in front of the car, but with no dazzle at a height more than one metre from the ground.—Xavier **Waché**: Quantitative researches on the ultra-violet spectrum of copper in aluminium. With aluminium containing 5 per cent. of copper, 35 copper lines were photographed for wave-lengths between 2179 and 3274 international units. Alloys containing 1, 0·5, 0·2, 0·05, 0·01, and 0·005 per cent. of copper (in aluminium) were examined with the same Hilger spectrograph, and the gradual disappearance of the lines shown. For the 0·005 per cent. alloy only the two lines 3247·5 and 3273·9 remained.—A. **Marcelin**: The isothermal compression and expansion of superficial solutions. By superficial solutions is meant such systems as a monomolecular layer of oleic acid on water. Two forms of apparatus are described for measuring the changes in the surface tension.—M. **Holweck**: A helicoidal molecular pump. A description, with diagram, of a modified form of Gaede pump, with details of the results obtained by it.—E. **Carrière** and **Cerveau**: Determination of the boiling-point and dew-point curves of mixtures of hydrobromic acid and water under a pressure of 760 mm.—E. **Darmois**: Polarimetric observations on tartar emetic, and tartrate and malate of uranyl. The precipitation of antimony oxide from ordinary tartar emetic solution by the gradual addition of potash has been followed by means of the polarimeter. The first reaction is the precipitation of Sb_2O_3 and formation of potassium tartrate: beyond a certain point the addition of more potash leads to the formation of a new lævorotatory compound, not yet isolated. The same method applied to the study of uranyl tartrate and malate leads to the conclusion that complex acids resembling tartar emetic are formed.—Mme. N. **Demassieux**: The equilibrium between lead iodide and the iodides of potassium and ammonium in aqueous solution.—F. **Bourion** and E. **Rouyer**: The association of mercuric chloride. From a study of the rise of the boiling point of solutions of mercuric chloride of varying concentration, evidence of the existence of the molecule $(HgCl_2)_3$ has been obtained.—André **Job** and René **Reich**: The existence of organo-magnesium compounds containing arsenic.—L. **Hackspill** and G. **de Heeckeren**: A new volumetric method of elementary analysis. The organic compound is burnt with copper oxide in a silica tube *in vacuo*, the water formed condensed at − 80° C., and the carbon dioxide and nitrogen pumped out and analysed. The water is afterwards allowed to react with calcium hydride, and the hydrogen measured. In this way the whole operation is reduced to a gas analysis.—Paul **Woog**: The hydration of hydrocarbons. The carefully dried oils were allowed to take up moisture from moist air, and the amount of water taken up was measured by the resulting change in the electrical conductivity. Difference in the amounts of water taken up under these conditions was observed for different classes of oil.—F. **Ehrmann**: Discovery of evidence of the Tyrrhenide in the region west of Bougie (Algeria).—G. **Pontier**: The fossil elephants of England: the presence of *Elephas trogontherii* at the extreme base of the forest bed of Cromer.—Pierre **Dangeard**: Remarks on the state of the oil in the interior of oleaginous seeds.—L. **Blaringhem**: The mosaic of the sexes in a hybrid of wild sorrel (*Rumex Acetosa* × *R. scutatus*).—Emile **Haas**: Experiments on the states of regional and relative adaptation of the retina.—Emile **Devaux**: The pace of development in interfecundity.—A. **Pézard** and F. **Caridroit**: Gynandromorphism in the Gallinaceæ.—Anna **Drzewina** and Georges **Bohn**: Retarded effects of the dilution of the sperm on the development of the egg of the sea urchin.—Edouard **Chatton** and André **Lwoff**: The evolution of the Infusoria of the lamellibranchs. The primitive forms of the phylum of the thigmotrichs: the genus Thigmophrya.

Prevention of Venereal Disease.

THE report of the Committee of Inquiry on Venereal Disease recently published[1] has been awaited with interest. It is a short report, as reports go, and it is an unanimous report, a result ardently desired by all those who have the matter at heart. The conflict of opinion on how best to root out venereal diseases from the community will still be remembered. It was voiced mainly by members of two societies, the National Council for Combating Venereal Disease and the Society for the Prevention of Venereal Disease, and was prominent both in the lay and medical press. The tone and publicity of the discussions seemed at the time regrettable, but it certainly aroused wide interest and helped to spread a knowledge of the main facts about the diseases, and in the end led to the calling together of this committee, the report of which, we believe, will give a fresh impetus to the attack on this world-wide infection. If the report should succeed further in uniting the fighting forces in this country, and make the two societies, which have in truth a common aim, join forces, this would be a crowning achievement. Both have expressed officially or otherwise their acceptance of the report. The co-operation of the two bodies would be so greatly for the good of the cause that we trust mutual goodwill will surmount any difficulties that remain.

The committee was a medical body appointed to consider the medical aspects of the subject under the chairmanship and vice-chairmanship of Lord Trevethin and Mr. Tomlin, K.C., respectively. Morals and medicine have always been liable to become entangled together, and on the subject of these diseases it is particularly difficult to avoid confusion in the public mind. The terms of reference to the committee made it very clear that the medical aspects only were to be considered. The terms were as follows:

"To consider and report upon the best medical measures for preventing venereal disease in the civil community, having regard to administrative practicability including cost."

The committee evidently realised that, in considering only medical measures for the prevention of venereal disease, it was not dealing with the whole problem of prevention. This is clearly set out at the beginning of the report—"having regard to the nature and origin of venereal disease the committee feel that . . . medical measures alone can never operate as an absolute preventive of disease, but their success must always depend largely upon the attitude towards them of the community and the co-operation of the community in securing their largest effect." How dependent a public

[1] Ministry of Health: Report of the Committee of Inquiry on Venereal Disease. Pp. 15. (London: H.M. Stationery Office, 1923.) 3*d*. net.

health authority is on public education and public co-operation for the effective control of any infectious disease was well demonstrated by the difficulties encountered in dealing with the recent smallpox epidemic at Gloucester, and yet smallpox is not usually a disease easy of concealment, there is no transgression of social standards implied in acquiring the disease, and it is of limited duration. All these facts should make it easy to control as contrasted with venereal diseases. In the latter, concealment is further aided by there being usually an absence of disablement from work; indeed, the symptoms may be so slight that the patient may be ignorant of being infected.

With these facts in mind, the conclusions of the committee on the question of notification of venereal diseases will, we think, meet with approval by the majority. The committee has reported against the introduction of notification in any form, on the grounds that as the disease can only become known to the doctor by a voluntary act on the part of the patient, concealment of disease is likely to follow notification, and it would prove a backward step. A modified form of notification, limited to those patients who, having presented themselves for treatment, failed to continue until cured, would impose a penalty on those who had at least shown some care for their health while letting the careless go scot-free. Another difficulty which is emphasised is the absence of any generally accepted standard of cure, and until this has been worked out, insistence under compulsion on a long course of treatment is wisely considered to be outside administrative practicability.

Turning to the controversial question of the *prevention* of disease by disinfection, either self-disinfection or skilled disinfection at the hands of a trained person, the committee agree that disinfectants do disinfect, given that the application is *thorough, prompt, and that the disinfectant is appropriate.* It stresses the fact that, to a large extent, exposure to infection takes place under conditions in which neither promptness nor thoroughness are likely to be exercised, and that the success of any public facilities for self-disinfection in the civil community is likely to be very small. But though in the opinion of the committee the majority would fail, a minority should succeed, and no obstacle should be placed in the way of private purchase of appropriate disinfectants. The law does not to-day permit the sale of *ad hoc* disinfectants. In order to obtain them the public must have either a doctor's prescription or be able to ask for what it wants by the exact name. The report advises the alteration of the law to allow of the sale of disinfectants in an approved form, with instructions for use approved by some competent authority. The suggestion that the Medical Research Council should be invited to undertake this task will, we hope, be received favourably. That body is already responsible for the standardisation of the arsenical compounds used in the treatment of syphilis, and its authoritative and independent position would make it particularly suitable for this undertaking. It is specifically advised that the commercial advertisement of such disinfectant should be prohibited. The importance of self-disinfection will find expression first among the educated classes, and from these will penetrate, as temperance did, into the minds of the community as a whole.

The general application of a system of skilled disinfection, which would necessitate the establishment and maintenance of buildings and also of attendants, is dismissed on the grounds of impracticability and cost, but in a later paragraph the committee shows an appreciation of the value of an experiment such as was made at the Manchester Ablution centres, and suggests that local authorities should be assisted to carry out experimental schemes for the prevention of venereal diseases, as for example in dock areas, where local conditions demand special measures. This, we think, is an excellent method of gaining administrative experience and of educating the public. It has already received official sanction in the past, and we hope that energetic local authorities will take advantage of the suggestion.

In addition, however, to medical measures for preventing disease in, or minimising the risk of disease to, persons exposed to infection, there are those for rendering non-infective, and curing, diseased persons. With regard to the latter, the committee remarks that

> "speaking generally, the general medical practitioner is not yet adequately equipped with the most advanced knowledge of venereal diseases and their treatment to enable him to deal competently with all the cases that come before him, and that an improvement in medical education in regard to venereal disease is necessary."

The present clinic system receives a full measure of approval, and extension and improvements are asked for. The importance of the educative work that is done in the clinic is stressed. The actual sufferer from the disease is almost the most important person to teach where limitation of the spread of disease depends so greatly on voluntary individual action. The doctor's words will always carry most weight with the patient, and we believe that most medical officers of clinics realise this and carry out this part of their work with self-sacrificing devotion; but patients may be stupid and ignorant and need often repeated explanations, the doctor's time and endurance are limited. Printed instructions and warnings are less impressive than the spoken word. The recommendation that trained social workers should be attached to the staff of clinics

to give supplementary teaching as well as general advice and assistance will, we hope, receive attention. We think that this is one of the most important of the recommendations. It is, in fact, no new departure, but at present the need for such work is not generally realised, and the number of clinics to which workers are attached is limited.

The work of ante-natal clinics is strongly commended. The position to-day as regards congenital syphilis is extremely encouraging. It seems within the bounds of possibility that inherited syphilis may cease to exist some day, so effective is the treatment of the syphilitic mother during pregnancy in securing a healthy baby, though sufficient time has not yet elapsed since the beginning of ante-natal treatment for any one to say that so insidious a disease as syphilis can be wiped out with certainty in every case.

A short paragraph summarily directs attention to three sources of disease which need tackling, although they present serious administrative problems. The three sources mentioned are infected immigrants, infected seamen, and infected mental defectives. The matter of arrangements for the treatment of infected seamen has already received much attention, but more remains to be done. The adequate care of the slightly feeble-minded and infected individual is of great importance to the community; as a focus of infection he or she may do an infinite amount of harm. No amount of teaching will develop a sense of responsibility, and temporary or permanent control is necessary.

The report shows us, in conclusion, how best to lay out our limited public money: first, in the treatment of disease; secondly, in teaching the public about the diseases; thirdly, in improvement of the conditions of living, *i.e.* houses, general education, and facilities for healthy recreation. It ends by directing attention to the decline in the numbers of sufferers from venereal diseases as shown by the clinic figures during the last two years. As, however, these still show an enormous prevalence of disease, no relaxation of effort can be allowed. The work of education on the subject of disease is, moreover, one that must be continued for all time. We cannot hope that venereal diseases will ever cease to exist, and their control will always depend on the enlightenment of the public. It is to be hoped that this report, issued at the very low price of 3*d*., will be widely read, for it concerns a subject of world-wide importance, and any summary discussion must necessarily leave untouched many important points with which it deals.

Lord Dawson, through whose efforts the committee and consequently this report came into being, is to be congratulated on the performance of a valuable public service.

Physics and its Applications.

A Dictionary of Applied Physics. Edited by Sir Richard Glazebrook. In 5 vols. Vol. 4: Light—Sound—Radiology. Pp. viii + 914. (London: Macmillan and Co., Ltd., 1923.) 63*s*. net.

THERE was a time, not so very long ago, when the student of physics could reach down from his shelves "Ganot" or "Deschanel" and, "laying flattering unction to his soul," could proceed to master their contents with the comforting if misguided assurance that here all useful knowledge was displayed. No such vanity of outlook is possible to the present-day student. The physics of this generation is teeming with such vitality, is making such gigantic strides and devouring at such a pace the boundaries of its sister sciences, that it threatens to overwhelm those of its devotees who vainly seek to achieve an all-round distinction.

The full truth of this is patent to the reader (and reviewer) who has attempted to survey the amazing compendium of knowledge in the various volumes of the "Dictionary of Applied Physics" which have been issued under Sir Richard Glazebrook's editorship. The Dictionary has become, as it was bound to become, a pillar of physical science and a fascinating mine of information, indispensable alike to the teacher, student, and investigator. One had been tempted to wonder whether the high standard set in the earlier volumes could be sustained, but a critical survey of the latest new-comer is amply reassuring. Sir Richard goes on, in fact, from triumph to triumph. Volume 4, which is devoted to light, sound, and radiology, shares in common with its predecessors a clarity, vigour, and "first-handedness" which are characteristic only of the investigator who is in close contact with his subject and endowed with the art of expounding it.

By far the greater part of the present volume is occupied with optical subjects. The first article is one by Dr. A. E. H. Tutton, who gives a short account of crystallography dealing, *inter alia*, with a number of ingenious instruments of his own design which have been employed in his extensive and well-known researches. Dr. John A. Anderson, of the Mount Wilson Observatory, refers briefly to the manufacture and testing of diffraction gratings. One learns that the general impression which prevails that the construction of a successful ruling machine is bound up with the manufacture of a perfect screw is erroneous. It is not difficult to make screws uniformly accurate to $\frac{1}{100,000}$ inch, but much more difficult to avoid errors due to faulty mounting. "The Theory of Diffraction Gratings," by Mr. J. Guild, of the National Physical Laboratory, forms a succinct though abbreviated companion article to Dr. Anderson's. Mr. Guild is

also responsible for an excellent summary of the physics of the human eye.

Several articles on glass follow, written from different points of view by Mr. E. A. Coad-Pryor, Mr. W. H. Withey, and the late Mr. Harry J. Powell. Mr. J. Rheinberg discourses on graticules and platinised glass; and the Paterson-Walsh height-finder, which found application in anti-aircraft work in the War, is described by Mr. J. W. T. Walsh.

Dr. W. W. Coblentz, of the Bureau of Standards, Washington, writes briefly on infra-red transmission and refraction data and includes a number of useful tables. An article on the kinematograph by Dr. J. W. French sets out in interesting fashion the main physical points which have had to be dealt with in bringing the instrument to its present state of development. Light filters are discussed by Dr. C. E. Kenneth Mees, and magnetic rotatory power by Prof. T. M. Lowry.

A long article on the optics of the microscope by Prof. A. E. Conrady deals comprehensively with a subject which normally receives inadequate attention. There is a wide gap between the optics of the text-book and that of the practical optician, and here we find the gap bridged by an acknowledged authority. Microscopy with ultra-violet light, and the enhanced resolution that it effects, are the subject of a very interesting article by Mr. J. E. Barnard.

Commander T. Y. Baker sets out in a noteworthy contribution the main underlying facts of navigation and navigational instruments. The mathematics of the Sperry gyroscopic compass are given, and the author makes reference to the atmospheric difficulties relating to the use of directional wireless. At times there appear to be long tracks in the atmosphere offering preferential facilities for the transmission of wireless waves, while at sunrise and sunset marked deviations may occur, directional errors of 20° or more being of frequent occurrence.

Mr. J. H. Sutcliffe unveils the mysteries of the specialised technique of ophthalmic optical apparatus. An article on optical calculations follows, by Mr. T. Smith, of the National Physical Laboratory, who, in association with Dr. J. S. Anderson, writes also on optical glass, including in the article a wealth of numerical data. The working of optical parts by Dr. J. W. French is a contribution of great practical interest, while Mr. T. Smith's very readable monograph on periscopes contains information much of which we imagine must here be set out for the first time. A lengthy and authoritative article by Mr. J. W. T. Walsh on photometry and illumination is notably up-to-date, and describes in detail the precision methods in use at the National Physical Laboratory and elsewhere. Photographic apparatus is treated very completely by Mr. C. W. Gamble, though the section on the modern development of aerial cameras calls for lengthier notice. Photographic lenses are dealt with by Mr. T. Smith.

Prof. C. G. Darwin sums up very briefly the present position of the quantum and radiation theories in physics, and this is followed very appropriately by Dr. W. W. Coblentz's admirable discussion of radiation from a practical point of view.

Two useful contributions on radioactivity and radium by Dr. E. A. Owen might advantageously have been permitted a lengthier treatment. The radium testing-work of the National Physical Laboratory has been of vital importance to the radium market in Great Britain, and we find the methods of test fully set out here. An article on radiology deals largely with the industrial developments of X-rays and the work of the National Physical Laboratory on X-ray protection.

The supreme importance of the short-base range-finder in the War needs no emphasis here. It forms the subject of an arresting contribution by Prof. F. J. Cheshire. The fighting services in Great Britain have favoured the "coincidence" type of range-finder, while the Germans employed the Zeiss "stereoscopic" pattern. In the laboratory there appears to be little in it as regards the two types, but under service conditions it is easier to train men to get accuracy with the coincidence type, an advantage which is emphasised when an operator is working under the intense nervous strain induced by modern warfare. The battle of Jutland permitted a comparison between the two types with almost identical base lines; and on a balance of evidence the coincidence type must, Prof. Cheshire states, be given first place.

Lord Rayleigh writes on the scattering of light by gases, a subject with which his name and that of the late Lord Rayleigh have noteworthy association.

Prof. E. H. Barton has a long and interesting article on sound and musical instruments in which is included a good, if somewhat brief, discussion of the question of the acoustics of buildings, a subject which is greatly to the fore at present, and is now receiving attention at the National Physical Laboratory and elsewhere. Attention is directed to the investigations of Webster, and in particular of the late Prof. Sabine in the United States, work which is not sufficiently known in Great Britain. We cannot afford to have many repetitions of the new County Hall of London acoustical fiasco. Prof. W. L. Bragg touches briefly on sound ranging, a branch of military activity in which, thanks largely to the Tucker hot-wire microphone, we enjoyed conspicuous advantage in France during the War.

Dr. T. R. Merton writes authoritatively on modern spectroscopy. A very informative article on spectroscopes and refractometers by Mr. J. Guild includes

a detailed account of the new National Physical Laboratory standard spectrometer. Spectrophotometry forms the subject of another article by Dr. K. S. Gibson, of the Bureau of Standards.

Major E. O. Henrici deals with spirit-levels and surveying. A recent development which does not find a place is the shaping of the level-tube so that the length of the bubble becomes independent of temperature changes. Prof. Horace Lamb contributes a short note on the vibrations of strings.

Prof. R. A. Sampson, Mr. T. Smith, and Dr. J. S. Anderson give between them an excellent and up-to-date treatment of telescopes, while Sir Richard Glazebrook himself is responsible for a number of short articles on optics. The volume concludes with an uninitialled contribution dealing comprehensively with the measurement of wave-lengths, which we gather from the list of contributors is by Dr. W. F. Meggers, of the Bureau of Standards. Dr. Meggers brings out in a useful summary table the striking fact that the range of electromagnetic waves known to science extends to more than 40 octaves, from the gamma rays of radium on one hand to the wireless and "electric" waves on the other. Since this article was written the gap of four or five octaves between ultra-violet and X-rays has been bridged, and now the only unexplored interval is one of two octaves between the infra-red and wireless waves.

We have perforce had to omit mention of many excellent contributions, but the reader will perhaps discern from what we have cited the quality of the fare that is set before him.

In conclusion, we consider that the substantial weight of the various volumes lends support to the view that they could advantageously be divided into two. We wonder, too, whether the "dictionary" mode of interpolating headings in alphabetical sequence between the various articles has much to justify it. Each volume is provided with an excellent index which could readily be made to serve every requirement, and will normally be the first resort of any reader seeking information.

G. W. C. KAYE.

The Thermal Decomposition of Wood.

The Destructive Distillation of Wood. By H. M. Bunbury. Pp. xx+320. (London: Benn Bros., Ltd., 1923.) 35*s.* net.

ONE hundred and fifty million tons of "wood waste" are produced annually, most of which, it is claimed, finds no useful application. Possible methods for the utilisation of this material are its destructive distillation to give valuable products, its employment directly as a fuel, its use in paper production, or its fermentation to produce ethyl alcohol. The first application, and wood distillation generally, although forming the subject of an ancient industry, has not hitherto been taken as the sole title of an English text-book. On account of the important economic problem involved the author has much to justify his effort, and from many points of view his book is a success. The descriptions of plant and processes for wood distillation and of stills and evaporators employed in the recovery of the distillation products are lucid, and while technical details have been considered, exactness in statement has been maintained.

From an economic point of view the efficient working-up of the products of distillation is all-important, and naturally this problem has received careful attention. The works chemist is confronted, among other problems, with the isolation of various organic compounds from his crude liquor condensate obtained when wood is destructively distilled. This heterogeneous product contains, in aqueous solution, acids, bases, alcohols, aldehydes, ketones and other substances, and in suspension, tarry matter of a highly complex composition. The author enumerates more than sixty compounds generally present, in addition to many others found in the crude oil from soft wood distillation. On distillation, after the acid products are fixed, various azeotropic mixtures, both binary and ternary, are formed, which makes the isolation of the individual compounds difficult.

The observations of Guillaume and Sorel on the purification of alcoholic liquors generally by a steam distillation method are not referred to, but developments from these researches are considered in detail, particularly in regard to the production of pure methyl alcohol direct from crude wood spirit.

Wade and Merriman in their classical work on constant boiling-point mixtures adopt the term azeotropic for such mixtures instead of hylotropic as proposed by Ostwald. Young and Lecat also prefer the word azeotropic with its more defined meaning. It is therefore to be regretted that in this volume the older term is again introduced. The author writes of a particular hylotropic mixture of 90 parts by weight of acetone, and 10 parts by weight of methyl alcohol, and later refers to this mixture as the "pure" or "theoretical" methyl acetone.

The author has given numerous flow sheets, but these, it is hoped, may be developed in a future edition, if possible on more quantitative lines. In the technical records of the Ministry of Munitions the idea of flow sheets and flow diagrams, not only qualitative but also quantitative, have been emphasised, and should set a standard.

The analytical methods are condensed into a dozen

pages, and offer no novel features. Owing to the drastic condensation employed, difficulties may occur in endeavouring to follow the directions. The alkalinity test for refined methyl alcohol is on the line of the Government "methyl orange alkalinity test" for wood naphtha for use as a denaturant, though this is not stated. In the abstracted form in which the test is described it may be misleading if applied generally.

The separate treatment of physical properties is a welcome feature in a technical volume of this type. The scope, however, is restricted, density and humidity only receiving consideration. The factor of wind velocity as an influence on humidity has not been indicated. More accurate practical means of measuring humidity (*e.g.* Assmann's hygrometer) are available than that described. The main source of reference appears to be the publications of the United States Forest Service.

On the assumption that wood cellulose first forms lævoglucosan on distillation, the author indicates how the two rings in this carbohydrate might be broken up to give many of the usual products obtained on the industrial plant. Pictet, however, obtained his lævoglucosan from a pure cotton cellulose, while it has yet to be shown that the cellulose from broadleaf or conifer trees will give appreciable amounts of lævoglucosan even on vacuum distillation. It must be recognised also that the non-cellulose portion of the wood has a profound influence on the nature of the decomposition. The author states that "it is now established that the complex carbohydrates found in plants are produced in the first place from formaldehyde which is photosynthesised in the leaves from CO_2 and water," and two references are given to the work of Baly and Heilbron. Possibly the word *established* is too strong at this stage in the chemistry of plant structure. The chemistry of wood is restricted to eighteen pages, and of necessity is incomplete. Two structural formulæ proposed by Irvine for cotton cellulose are given, but it is not made clear that even the resistant cellulose in wood has yet to be shown to be of similar constitution. Indication should be made to the fact that Irvine obtained his 2 : 3 : 6 trimethyl glucose from the highly methylated cellulose by hydrolysis.

It is stated that charcoals can be represented as $C_{16}H_{10}O_2$, and in a footnote it is implied that the formula is not intended to represent a single chemical compound. Again, in another connexion $C_{10}H_5O$ is indicated to be "primary charcoal," and $C_{30}H_{20}O_3$ to be "secondary charcoal." Giving definite molecular formulæ, rather than percentage composition only, to these residual products is not considered sound in the present state of our knowledge.

Charcoal was originally the main product sought after in wood distillation for metallurgical needs, but a substitute has been found in coke. Acetic acid and methyl alcohol are now the principal products desired. Organic and biological chemistry are, however, making rapid strides, and soon these products may possibly be produced more cheaply by processes other than the thermal decomposition of wood. The gases once considered unimportant may yet become the mainstay of the wood distillation process. The outlook, however, at present is not very hopeful, at least in coal-producing countries. Recent developments, which are very well described by the author, have been along two lines—the carbonising of wood in gas retorts and in gas producers or generators.

The text shows the mark of careful editing, and only a few errors and misprints have been noticed. In some instances a lack of uniformity in units occurs. Again, such statements as "Add H_2O_2 to decompose the remaining $KMnO_4$," or "1 gram $CO_2 = 1.045$ grams of H.COOH," might be expressed otherwise. There is too great a tendency to use molecular formulæ as a kind of shorthand in the text.

The volume is more in the nature of a well-written compilation of current literature than a record of the author's personal experiences. It contains one hundred and twenty tables, many of them full-page, as well as more than a hundred illustrations and photographs all excellently reproduced. In the printing and arrangement of the book there is little further to be desired. The only serious complaint that can be offered is that the price tends to restrict the book to the reference library rather than to place it on the shelves of the industrial chemist and technical student, where it would be extremely useful.

JOSEPH REILLY.

Clinical Pathology.

A Manual of Clinical Diagnosis by Means of Laboratory Methods, for Students, Hospital Physicians and Practitioners. By Dr. Charles E. Simon. Tenth edition, enlarged and thoroughly revised. Pp. xxiv + 1125 + 23 plates. (London: Henry Kimpton, 1922.) 42*s.* net.

IN any branch of knowledge actively progressing in many divergent directions it is of course difficult to keep the whole field of investigation in proper perspective, and the very keenness of the workers in the different divisions tends to keep them immersed and somewhat solitary in their own grooves. This disadvantage specially concerns medicine, in which it is most desirable that the clinicians and the laboratory workers should be in close and constant touch with each other; to some extent this is effected by clinical pathology, and the clinical pathologist

should be the equal and companion of the clinical physician. One of the deservedly best known text-books on this important subject is Dr. Charles E. Simon's, first published in 1896, the tenth edition of which is now before us. During its life of more than a quarter of a century, it has served as a kind of index of the extent of the subject, and in this connexion it may be noted that the present edition is more than double the size of the first. Dr. Simon, who speaks with the authority of a former professor of clinical pathology, a post he has given up for that of lecturer in medical zoology in the School of Hygiene and Public Health of the Johns Hopkins University, Baltimore, is emphatic in his opinion that even now too little attention is paid to clinical pathology by hospital physicians, and that accordingly students and general practitioners are without an accurate idea of the value of this means of diagnosis. Dr. Simon advocates the establishment in every medical school of a chair of clinical pathology, and that its occupant should in every respect rank equally with the clinical teachers.

The subject matter of clinical pathology is so constantly increasing that, as the author admits, it is impossible for a text-book to be actually up-to-date. The truth of this is indeed shown in this instance, for the date of its going to press is apparently June 1922, and there is not any reference to Hijmans van den Bergh's test for bilirubins in the blood serum, now much employed in the differentiation of obstructive from other forms of jaundice, which was first brought prominently to the notice of British readers by Dr. J. W. M'Nee's paper in the *British Medical Journal* of May 6, 1922.

The present edition has 273 pages more than its predecessor, and has been largely rewritten, especially the section on parasitology, which now occupies more than 100 pages and is illustrated by fifty figures.

The subject of the blood takes up more than a fourth part of the volume, and, naturally from the great interest taken in America in the subject of basal metabolism, gives the methods of estimating the hydrogen-ion concentration of the plasma, the determination of the carbon dioxide combining power of the plasma, and the determination of the alveolar carbon dioxide tension. The estimation of the blood sugar and the tests for renal efficiency have been brought up-to-date, though perhaps more might have been said about the lævulose test in connexion with hepatic insufficiency. The serological section has been entirely rewritten, and the author's method of carrying out the Wassermann reaction for syphilis is fully detailed and critically compared with that of Noguchi. It may be noted that in the section on parasites, under the heading of Leptospiras, the genus isolated by Noguchi, the organisms of spirochætosis icterohæmorrhagica and of yellow fever are described with a plate.

The section devoted to the alimentary canal contains a good account of Rehfuss's fractional analysis of the stomach contents, which gives an insight into the entire cycle of gastric digestion, including both the secretory and the motor activities of the viscus. Lyon's method of obtaining bile by means of the duodenal tube is described, but the recent discussion on the validity of the distinction of the three categories of bile—from the common bile duct, the gall bladder, and the liver—obtained by this procedure is not mentioned.

In the second part of the work, occupying about one-quarter of its pages, the diseases are arranged in alphabetical order with the essential points in their laboratory diagnosis. In conclusion, this manual may be confidently recommended to clinical pathologists as a valuable source for daily reference.

Argumentum ad Communem Sensum.

Universe. By Scudder Klyce. With Three Introductions by David Starr Jordan, Prof. John Dewey, and Morris Llewellyn Cooke. Pp. x+251. (Winchester, Mass.: The Author, 1921.) 10*s*.

WE are told on the highest authority that there are things which God has hidden from the wise and prudent and revealed unto babes. The extraordinary claim which Mr. Klyce makes in this book is that the whole riddle of the universe has a verifiable solution which can be made plain to a child of six. Quantitatively indeed, the child might find this book an overdose, but qualitatively it would understand the argument. The author speaks from knowledge, for he tells us he has tried it and found it is so. The preliminary prospectus is so extravagant, and the account of the conception and production of the book (which we are told was rejected by eighteen publishers and turned down by twenty-five financiers, and consequently had to be printed by the author in a press set up by himself for the purpose) is so amusingly naïve that the serious student would probably decide on *a priori* grounds that its value is zero, were he not arrested by the names of three distinguished scholars who have made themselves sponsors for the author and his work. Two of them, Prof. J. Dewey and Dr. David Starr Jordan, enjoy a world-wide reputation. We are compelled, therefore, to treat Mr. Klyce's book seriously.

The first distinction to which we are introduced is that between qualitative and quantitative problems. It is the former which are easily solved: the latter are infinite in number, and as life is finite we cannot exhaust them. It is in regard to the qualitative problems in religion, science, and philosophy, that Mr. Klyce thinks we are being fooled by a trick of language, for

this in his view is what "logic," which he opposes to "commonsense," is. Get behind language, behind the sign which merely serves the purpose of a finger-post, to the thing signified, and the problem disappears. We call to mind that Descartes said, "Give me matter and movement and I will make the world." But we also remember Pascal's remark concerning it, "Quand cela serait vrai, nous n'estimons pas que toute la philosophie vaille une heure de peine."

Mr. Klyce divides his task into three parts. Let us leave the philosophy and religion and attend only to the concrete science. The principle and method are the same in all three parts. All difficulties turn out to be a "trick of language," and, when this is exposed, the sophistication is obvious and the truth becomes dull in its very obviousness. When we come to the definite treatment of mathematics and physics the problems prove to be variations of the single problem of the One and the Many. It is not easy to give a clear example, notwithstanding the claim of lucidity, because the text is so laden with diffuse parenthetical remarks. Some notion of the principle may be gained, however, if we reproduce *verbatim* a few sentences from the treatment of Newton's three laws of movement, with which Part II. on Physical Science begins. "Clearly his first law is substantially equivalent to what we started with in formulating language—the verbal meaning of a One which we may arbitrarily divide. It is equivalent in detail to: *all* matter (the One), as such, has the 'property' of *not* changing. And that is no 'property' at all, but an assertion that 'all matter' is *not-divided*—which is a verbal truism at the beginning of monotheistic speech." And this: "It may be reasonably held that his first law is an assertion of or agreement to use God the Father or One words. The second law, then, is a statement of God the Holy Ghost, or 'force.' And we shall see that the third is explicit statement of God the Son."

The book covers very complete ground, and the author shows that he is acquainted with the modern mathematical and physical theories which he discusses in the above manner. There is a certain puzzling inconsistency, however, in finding in logic the principle of "unification" and then condemning logic as a trick. But whether or not readers are convinced by the author's argument, they cannot fail to be interested in the psychology of the author himself which it reveals. Yet it can scarcely have been this which has led Prof. Dewey to write the prologue. Mr. Klyce would render an inestimable service to philosophy if he would persuade Prof. Dewey to add an epilogue; for his prologue leaves us in some doubt as to whether he himself has verified this verifiable solution of the riddle of the universe.

Our Bookshelf.

The Study of English Speech by New Methods of Phonetic Investigation. By Dr. E. W. Scripture. (Published for the British Academy.) Pp. 31. (London: Oxford University Press, 1923.) 3s. 6d. net.

DR. E. W. SCRIPTURE's memoir deals with the employment of instruments and apparatus which "not only record the facts of speech automatically and permanently, but also provide for interpreting them with microscopic accuracy," and discusses a number of linguistic problems which have been or might be approached by these means. Philologists are divided more or less into two camps by the assertions of Prof. Sievers, of Leipzig, as to the intonation of ancient Hebrew, Greek, Swedish, Gothic, etc. Rejected by some as having no objective basis, his inferences are accepted by others as authoritative, and are now finding their way into the text-books, as in Streitberg's "Gotisches Elementarbuch." Meanwhile the number of phonetic laboratories on the continent is increasing. There are workers in this field in Paris, Hamburg, Prague, Uppsala, Utrecht, Louvain, Kristiania, and other places.

The recent correspondence on Shakespeare's Verse in *The Times Literary Supplement* (closured April 26) shows how attractive such problems of analysis can be to those who like to work at something difficult, and suggests the need of concentration. It is difficult to believe that Shakespeare's lines have ever been more admirably delivered than by Sir J. Forbes-Robertson. A gramophone record allows those prosodists who judge by ear to revise their impressions indefinitely, while a mechanical enlargement of the curves on the disc permits the metrical proportions of duration, amplitude, and frequency to be measured to a high degree of exactness, at the cost, certainly, of much highly skilled labour.

Théorie mathématique des phénomènes thermiques produits par la radiation solaire. Par Prof. M. Milankovitch. Pp. xvi+339. (Paris: Gauthier-Villars et Cie, 1920.) 20 francs net.

THE earlier chapters of this work are concerned with finding formulæ for the amount of "insolation" or reception of radiation from the sun at various latitudes on planets, first without atmospheres, and secondly with them. The formulæ involve the reflective power of the planetary surfaces; the propagation of heat-waves in the soil and the effects of change of obliquity and eccentricity of orbit are also considered. It is pointed out that a rapid rotation diminishes the difference between diurnal and nocturnal temperatures while slow rotation increases it.

The second part of the book applies the formulæ obtained to the case of the four inner planets and the moon. For the earth the author discusses secular changes of climate depending on changes of obliquity and eccentricity, and regards Croll's theory as still tenable, being thus in opposition to most recent climatologists.

Prof. Milankovitch concludes that the thin air on Mars allows a considerable amount of heat to reach the soil by day, but that the nights are intensely cold.

Mercury and the moon are concluded to suffer from great extremes of climate, while the high albedo of Venus indicates that much light and heat is reflected without reaching the surface, so that the temperature of the latter may be moderate. A. C. D. C.

Handbuch der biologischen Arbeitsmethoden. Herausgegeben von Prof. Dr. E. Abderhalden. Lieferung 94. Abt. IX: Methoden zur Erforschung der Leistung des tierischen Organismus. Teil 1, Heft 3: Methoden der zoologischen Forschung. Pp. 439-584. (Berlin und Wien: Urban und Schwarzenberg, 1923.) 6.3 Schw. francs.

THE present number of this extensive work is devoted to methods of zoological investigation. The first article, by L. Neumayer, deals with the fixation of tissues for histological purposes, and provides a useful, well-arranged account of the various fixatives, with notes on the different tissues to which they are applicable. There are also abundant references to the literature of the subject. The second article deals with entomological technique, and is contributed by Albert Koch. In this account are included descriptions of all the various entomological methods of collecting and mounting specimens, rearing larvæ, and the preparation of material for histological study. The third article, by W. A. Collier, deals with the determination of age in fishes by means of growth phenomena afforded by the otoliths, opercular bones, and scales.

The last article is by Th. Mollison, and treats of serum diagnosis as a test of affinities as applied to zoology and anthropology. Previous parts of this work have already received notice in our columns, and the present contribution is no exception to the general standard of excellence that characterises this encyclopædic treatise.

La Lampe à trois électrodes. Par Prof. C. Gutton. (Recueil des Conférences-Rapports de Documentation sur la Physique. Vol. 5, 1re Série, Conférences 11, 12, 13. Édité par la Société *Journal de Physique.*) Pp. 181. (Paris: Les Presses universitaires de France, 1923.) 15 francs.

RADIO engineers will welcome this book by Prof. Gutton. He starts by giving a complete account of the physical phenomena utilised in the three terminal thermionic valve. Full use is made of characteristic curves, and formulæ given by Richardson, Langmuir, and Clerk Maxwell are quoted. In the second chapter several good types of apparatus suitable for amplifying are described and approximate formulæ are obtained for them. In the next chapter oscillating circuits are given, the theory being well and clearly explained. The theory of the methods of using filters to eliminate harmonics is also given. Next comes the theory of detectors and detecting circuits. Finally the arrangement to get "negative resistance" is shown and the methods of obtaining high frequency currents by utilising suitable valves are described and their useful applications in making electric measurements are explained. The author defines the resistance of a circuit as "negative" when an infinitesimal reduction of the terminal voltage produces an infinitesimal increase in the current.

Biologie der Tiere Deutschlands. Bearbeitet unter Mitwirkung zahlreicher Fachleute und herausgegeben von Dr. Paul Schulze. Lieferung 1. Teil 2: Spongiaria. Von P. Schulze. Teil 3: Cnidaria. Von P. Schulze. (Berlin: Gebrüder Borntraeger, 1922.)

THIS is the first of a series of booklets giving an account of the general biology, physiology, life history, and ecology of the animals comprising the German fauna. Marine forms are omitted from considerations of space. No systematic treatment is attempted, and only so much of the anatomy, histology, and embryology of the animals is included as is necessary for a proper understanding of their biology. It is essentially a book of Nature study, wholly excellent in conception, popular in intention and strictly scientific in treatment. It will be issued in a series of pocket volumes, on the lines of Brauer's "Süsswasserfauna," and when completed will form a companion work to Brohmer's "Fauna von Deutschland," in which the systematics of the groups are dealt with. The work is intended for use in the field by students, teachers, and field naturalists generally, and should be of the greatest value in stimulating the study of Nature on a scientific basis. There is room for a similar work on the British land and freshwater fauna; but until such appears this book will, at any rate partially, fill the need.

The Common Birds of India. Described by Douglas Dewar and illustrated by G. A. Levett-Yeats. Vol. 1. The Sportsman's Birds, Wild Fowl, Game Birds, and Pigeons. Part I. Pp. viii+44. (Calcutta and Simla: Thacker, Spink and Co., 1923.) Rs. 2.8.

MR. DEWAR contemplates a series of volumes (five in all, of about 140 pages each) dealing with the birds of India as a whole and forming a profusely illustrated work of a popular nature designed for the guidance of sportsmen and the non-scientific resident. The first part deals with the ducks, swans, and geese, and though the style is too journalistic, the matter is excellent as a good account of the salient features of these birds and of their general natural history. A list of vernacular names and an easily used key for ready identification are two features of special value which we hope will be continued in later volumes. Mr. Levett-Yeats's illustrations add considerably to the usefulness of the work and are worth the expenditure of a little more care in reproduction. There is room for this book, and we hope that Mr. Dewar will receive sufficient support to justify him in carrying the project to completion.

La Vie des atomes. Par Prof. A. Boutaric. (Bibliothèque de Philosophie scientifique.) Pp. 248+4 planches. (Paris: E. Flammarion, 1923.) 7.50 francs net.

PROF. BOUTARIC deals in an interesting way with the recent advances in physics which led to the present view of the structure of the atom. The last part of the subject is treated only very briefly, but the fundamental experiments are clearly reviewed. The treatment is non-mathematical, and the book will be read with interest by those who wish to obtain some conception of the radical changes in outlook which have resulted from recent work. There is no index.

Letters to the Editor.

The Mass-spectrum of Copper.

THE number of elements of which the isotopic nature has been determined is now large enough to give considerable weight to statistical relations. Among elements of odd atomic number two definite empirical rules stand out. The first is that none of them consists of more than two isotopes. This has no exception so far. The second is that the more abundant of the two constituents, or both, will be of odd atomic weight. The only exception to this is the element nitrogen; moreover, the only even isotopes at all are the weaker constituents of lithium and boron. That both of these rules should be violated by copper having the three isotopes 62, 64, 66, announced recently by Prof. Dempster, seemed therefore excessively improbable.

I have now been able to obtain the mass-spectrum of copper by employing cuprous chloride in the accelerated anode ray method used with the mass-spectrograph. The lines are faint, but their evidence is conclusive since they appear at the expected positions 63 and 65 and have the intensity ratio, about 2.5 to 1, predicted from the chemical atomic weight 63.57. The positions of the lines could be determined with great accuracy by comparison with the line 56 due to iron derived from the anode container. No deviation from the whole number rule was observed.

With regard to Prof. Dempster's results (NATURE, July 7, p. 7), it is very suggestive that the intensity and grouping of the lines he ascribes to copper agree exactly with those of the strong isotopes of zinc. It seems possible, therefore, that they are due to the presence of traces of that element either in the copper or more probably, together with the rubidium he mentions, in the furnace material.

F. W. ASTON.

Cavendish Laboratory, Cambridge, July 25.

Polar Temperatures and Coal Measures.

FOR some years I have held a view of the possible origin of some at least of the coal measures of the polar regions that is not found in the ordinary geological text-books. After discussing it with a dozen friends who are geologists, and some of them specialists in glacial geology, I have concluded—somewhat to my surprise—that the theory is new. A short statement of the theory may therefore be desirable.

It is generally considered that certain plants are not limited in their geographic range, by no matter how intense a cold in winter, if only they have an adequately hot summer. Apparently this hot summer may be very short and still the plants prosper. Notable examples are the black spruce of northern Canada and similar trees in the northern part of the Old World.

In the western hemisphere I have examined specimens of coal from 79° north latitude. So far as the material could be identified it was coniferous. In other deposits almost equally far north I have found gum and pine cones.

The northern limit of conifers in North America at present is between 68° and 69° north latitude. That this limit is determined not by intensity of cold in winter, but by lack of heat in summer, is shown by the luxuriance of the black spruce and several other trees in the mountain valleys of the Yukon, where the minimum temperatures in winter are from 10° to 20° lower than at the northern limit of trees. This northern limit is therefore determined by the proximity of the Arctic waters chilled by floating ice, which lower the summer temperature.

The United States Weather Bureau frequently reports temperatures above 90° in the shade, observed under standard weather bureau conditions, at Fort Yukon in Alaska, just north of the Arctic circle. The Bureau occasionally reports 95° F., and has reported even 100° F. The Canadian Weather Bureau reports nothing above 88° F., but that is because its northern stations are strung out at intervals along the northward flowing Mackenzie River. On two journeys down this river (1906 and 1908), and from common report as well as from weather bureau observations, I know that there is on most occasions a wind blowing with almost the steadiness of a trade up the Mackenzie valley from the Polar Ocean. Explorers who have been in the Canadian Arctic, away from the Mackenzie wind-trough, have observed temperatures much higher than those recorded by the Weather Bureau.

We have, then, observational confirmation of the theory, according to which the polar regions receive about as much heat for five weeks in summer as does the equator.

Most observers reporting climate from the polar regions have done so from locations on shipboard or on a sea-coast, where the downpour of the summer sun's heat has been neutralised by the chill of the ocean stored up through a long and cold winter. It is true that the ground in the Arctic is frozen, and that the temperature of the earth 40 or 50 ft. down has been found to be about +10° F., whereas the ocean 50 ft. down would have a temperature about +29° F. Soil and even rock are, however, poor conductors of heat, and the ground chill is imprisoned, while the ocean chill is freely liberated. Furthermore, the great heat of summer produces on most land surfaces a mat of vegetation, which is an even poorer conductor of heat than the earth itself. This is why a thermometer 6 ft. above a damp meadow in the arctic regions of Alaska, protected from the sun's rays in the usual weather bureau way, is able to record temperatures ranging from 60° F. to 100° F. almost every day for a period of several weeks in midsummer.

Consider now what the weather conditions in the Arctic Regions would be if, instead of the present ocean ranging in depth from one to three miles, we had an extensive low land—say a continent as low and as flat as Australia, with the North Pole near the centre of it. Better still, assume that the low land of northern Siberia, with physical characteristics such as it now has, were to extend to and beyond the North Pole, including a large part of the Canadian Archipelago, or even joining up with North America itself. Remembering that the sun delivers about as much heat in the Polar Regions as in the Tropics in midsummer, and also the observation that frozen ground has little effect upon the temperature of the air above it, then according to recorded midsummer lowland temperatures at present in the Polar Regions, we should have at the North Pole July heat of so-called "tropical" intensity, and conditions all over the Arctic suitable for dense forests of black spruce and other trees and shrubs, without calling upon any further alteration in environment—such as different chemical composition of the atmosphere,

a shifting of the earth's axis, a change in the shape of the earth's orbit, or an increase of solar radiation.

It is well known that perpetual ground frost to within 10 or 15 inches from the surface does not interfere with the prosperity of a black-spruce forest. At Fort Macpherson, N.W.T., Canada, for example, we have trees a hundred feet high growing straight and close together, and yet I have observed in midsummer that the perpetual frost around their roots was less than a foot below the surface.

As stated above, I do not offer this explanation of certain of the coal measures in connexion with any allegation that the Arctic was once an extensive low land, but merely as an hypothesis which can be called upon in case other evidence shows that extensive low land may once have existed there.

Coal has been found in the Antarctic no less than in the Arctic. The Antarctic is at present in large part an extremely high continent, but it is at least worth considering whether it may not have been a low land at the time when the coal was formed there.

It has been abundantly shown that permanent snow on land in the polar regions depends on altitude and precipitation rather than latitude. Nansen has said that on the low land of northern Siberia no permanent snow has been found, and that he feels certain none can be found. Many travellers, including myself, have reported from northern Canada, northern Alaska, and from the islands to the north of Canada, the total absence of bodies of permanent snow large enough to be called glaciers, though there are small snow-drifts at the end of summer in the shadowed bottoms of deep ravines in some of the Canadian islands. Greenland is 90 per cent. covered with ice, but the largest ice-free area in Greenland is near its northern end, showing that altitude and precipitation rather than latitude are the controlling factors. The smaller glaciers of Franz Josef, Spitsbergen, Ellesmere, Heiberg, North Devon, and the one or two small glaciers of Baffin Island, depend similarly on altitude and precipitation. A mere change of altitude without change of area might therefore remove the whole ice-cap of Antarctica—or certainly it could be removed by a reduction to a general level below 2000 ft. and perhaps a slight increase in area. With the ice once gone, only the Antarctic shores would be kept cool in summer by the sea, the interior promptly adopting the extremely hot June and July weather now found in the Arctic lowlands, thus bringing conditions suitable for spruce forests and the development from them of beds of coal.

VILHJALMUR STEFANSSON.

The Trichromatic Theory of Colour Vision.

THE history of the spread of knowledge regarding the Young-Helmholtz theory of colour vision is a very curious one. As in the case of all other great theories, its range of possible application far exceeds the demands made upon it for the explanation of actual facts. Limitations have to be imposed upon it here and there in answer to inquiry as to which choice out of several has been the one adopted by Nature. This process is in accordance with the development of all great theories. In the earlier stages powerful restrictions are adopted in order that advancement may be made. When these are found to be too restrictive a wider postulate is made so as to include a wider group of facts within the scope of the theory; and, the whole development being simple and direct, the theory at last stands forth as no longer a theory but a fact greater and wider than any of the groups of facts which are contained within its bounds. Thus the electron theory is now, apart from certain tentative developments, a fact standing upon as wide a basis of experience as any so-called fact of which we are cognisant.

This statement also holds in the case of the kinetic theory in general. But, if the great developments by Clausius, Maxwell, and others more recently, were unknown; if nothing were known beyond the results of the early restrictive postulate of perfectly hard, spherical, smooth, and elastic atoms; commentators of to-day might readily be found condemning the theory, and asserting that it could not explain the facts which the recent workers have shown to be direct and simple consequences of its naturally developed postulates. This, or rather worse, is exactly the position with regard to many present-day criticisms of the trichromatic theory of colour vision. These are evidently made in entire obliviousness of developments actually made by Helmholtz himself.

A still more curious condition which subsists is that the commentators are not entirely worthy of blame. For the later developments have never become common scientific property in Britain, while the early developments became widely known.

As examples of the criticisms I give some statements taken from Dr. Edridge-Green's book on colour vision. In doing so I desire to make it clear that I am making no attack upon his valuable and interesting work; I am only replying to his strictures upon the Young-Helmholtz theory, in which he, in my view, inadvertently draws quite undeserved and wrong conclusions. In chap. xxx. he gives six arguments which he holds to be conclusive against the Young-Helmholtz theory of colour vision, and eight against the Young-Helmholtz theory of colour blindness. I assert, on the contrary, that the theory gives a simple and direct account of the phenomena in each case; and I give the mode of deduction in five cases.

"The theory does not explain why there should be a defect in hue perception in those who have lost one of their sensations." Now, actually, the theory explains it beautifully. Thus in any stretch of wavelengths in which two of the three sensation curves have opposite slopes, hue discrimination is correspondingly strong. Therefore annulment of one of these curves diminishes it.

"The theory does not explain why many dichromics have a luminosity curve similar to the normal." This is an example of overlooking the later developments of the theory. If the dichromasy arises from fusion of two of the sensation curves, the distribution of luminosity may be unaltered.

"There are not two or three definite varieties of colour blindness, as there should be according to the theory." Here again there is oversight. In the hard-smooth-elastic-spherical-atom stage of the theory this might have been asserted. Actually, according to the theory as left by Helmholtz, there may be a doubly infinite variety of cases of colour blindness.

"How could the loss of half of a hypothetical green sensation cause dichromatism?" The answer is simple. Given one sensation curve intersecting the other two, if lessening of its ordinates by one half makes it fall entirely within the others, dichromasy is present.

On p. 210, and also in the *Phil. Mag.*, Nov. 1922, Dr. Edridge-Green describes another case. "A man with shortening of the red end of the spectrum and normal colour discrimination will put together as exactly alike a pink and a blue or violet much darker. If, however, the pink and blue be viewed by a normal sighted person through a blue-green glass which cuts off the red end of the spectrum, both will appear identical in hue and colour. This

proves conclusively that the defect is not due to a diminution of a hypothetical red sensation, because all the rays coming through the blue-green glass are supposed to affect the red sensation, and yet we have been able to correct the erroneous match by the subtraction of red light."

Now the question of a longer or shorter spectrum with otherwise absolutely normal vision is one which can be dealt with equally easily by all theories. To show the power of the Young-Helmholtz theory, I shall take the most extreme case possible, that in which the peculiarity amounts to dichromasy. Let the pink and violet colours be represented by $x_1\mathrm{R}+y_1\mathrm{G}+z_1\mathrm{B}$ and $x_2\mathrm{R}+y_2\mathrm{G}+z_2\mathrm{B}$ respectively, in the usual trichromatic notation; and let the colour abstracted by the blue-green glass be $a_1\mathrm{R}+b_1\mathrm{G}+c_1\mathrm{B}$ in the case of the pink, and $a_2\mathrm{R}+b_2\mathrm{G}+c_2\mathrm{B}$ in the case of the violet. So the colours seen by the normal eye are $(x_1-a_1)\mathrm{R}+(y_1-b_1)\mathrm{G}+(z_1-c_1)\mathrm{B}$ and $(x_2-a_2)\mathrm{R}+(y_2-b_2)\mathrm{G}+(z_2-c_2)\mathrm{B}$ respectively. If these appear to be identical, we have $x_1-x_2=a_1-a_2$, $y_1-y_2=b_1-b_2$, $z_1-z_2=c_1-c_2$. These are the relations which must subsist amongst the unifiable colours and the colours absorbed by the unifying medium. Now let the dichromasy correspond to the condition $\xi\mathrm{R}+\eta\mathrm{G}+\zeta\mathrm{B}=\mathrm{O}$. The pink and violet are then expressible as $(x_1-z_1\,\xi/\zeta)\mathrm{R}+(y_1-z_1\,\eta/\zeta)\mathrm{G}$ and $(x_2-z_2\xi/\zeta)\mathrm{R}+(y_2-z_2\eta/\zeta)\mathrm{G}$ respectively. These being identical, we have $(x_1-x_2):(y_1-y_2):(z_1-z_2)=\xi:\eta:\zeta$, which are the conditions for Dr. Edrige-Green's case. The trichromatic theory, so far from being helpless, as he asserts, not merely accounts generally for the phenomenon, but tells quantitatively as well as qualitatively what is happening. W. Peddie.

Distribution of Megalithic Monuments.

Mr. O. G. S. Crawford, in Nature of May 5, p. 602, criticises what he terms my "speculations" concerning the distribution of megalithic monuments in England and Wales. I am sorry that apparently he did not trouble to read the paper, and to see exactly what I had to say on the matter. My aim was to urge that there is a connexion, in England and Wales, between the distribution of megaliths and certain geological formations, the Granite in Devon and Cornwall, the Chalk in Dorset and Wilts, the Lias in Gloucester and Oxford, and so forth. In this I found that I had been anticipated in part by Mr. Crawford himself. Where we differ, of course, is in the interpretation of the evidence.

An examination of the paper will show Mr. Crawford that I am well aware of the difficulties involved in the theory that the builders of megalithic monuments were attracted to this country by the stores of gold, copper, lead, and so forth, that it contained, and that I discussed the very points to which he directs attention. It must never be forgotten, however, that megaliths are found in all parts of the world, and that possibly the explanation of the presence of these monuments in one country may serve to explain their presence elsewhere. All I have done is to put forward the theory, based on evidence from all parts of the world, that the megalithic civilisation of western Europe was derived from a metal-using civilisation in the Ancient East.

The attention of all who are interested in the matter is being directed to the excellent work now being done by Mr. Crawford at Southampton, and we are all eagerly expecting the publication of the fresh distribution maps of megalithic monuments that Mr. Crawford promises us. But, admirable as such work is, the final solution of the problems presented by these monuments may, after all, come from a wide survey of facts derived from all parts of the world, and not necessarily from detailed work in a limited part of the field. The Concentration of Hæmoglobin in Blood Corpuscles.

I have very little doubt that Dr. Gorter is right in suspecting that the method which is commonly used for determining the volume of the red blood corpuscles by centrifugalisation is not trustworthy (Nature, June 23, p. 845). Whether the red corpuscles are biconcave discs or hollowed cones, or indeed, whatever their shape may be, they cannot be packed together without leaving spaces between them unless they are deformed: and if they are deformed there is every reason to be suspicious about their water content remaining unaltered.

The usual method is to centrifuge the blood until the volume of the cells ceases to become smaller, the apparatus generally making 3000 to 5000 revolutions a minute with a disc of something less than a foot. It is easy to convince oneself that the final result depends on just how the process is carried out, for it is different if the blood is first gently centrifuged, say at about 2000 revolutions, and then exposed to the full speed, from what it is if the high speed is used from the beginning. So dependent is the figure obtained on the precise details of the method that, if real comparisons between different bloods is required, it seems to be essential that they must be in the centrifuge simultaneously.

The method seems never to have been examined critically. What is wanted is a comparison between it and the results calculated from the concentrations in whole blood and in plasma of some substance present in plasma and not in red corpuscles, which can be estimated with a high degree of accuracy. Without some control of this kind the method must, for absolute values at any rate, remain under suspicion.

Effect of Plant Extracts on Blood Sugar.

Our studies in connexion with insulin led us to the conception that carbohydrate metabolism is performed by an oxidising ferment mechanism. This theoretical conception induced us to test vegetable material, known to contain oxidases and peroxidases, for oxidising substances having an insulin-like action. In December 1922 we injected 5 c.c. of juice from a new potato intravenously into a 1500 gm. rabbit and noted a fall of blood sugar in one hour from 0·17 to 0·13 per cent. Since then we have found that sterile pieces of raw potato, and juice expressed from these, introduced into a glucose solution, after incubation for twenty-four hours at 37° C., caused this to lose from 26 to 36 mg. of glucose per 100 c.c. These results were published in the *Jour. Amer. Med. Assoc.*, June 2, together with results indicating a diminished glycolytic power of blood from diabetics.

Winter and Smith published a note in the *Journ. Physiol.* 57, 40 (Nos. 3 and 4), 1922, which reached the United States in April last, and in Nature of March 10, p. 327, stating that they had obtained an insulin-like substance from yeast.

Collip, in Nature of April 28, p. 571, states that he, working independently, found an insulin-like substance in various vegetables, in yeast, and in clams. Collip's studies on insulin are of inestimable

value and made it possible to obtain insulin from animal pancreas in quantities for practical use. He expected to find an insulin-like substance wherever glycogen occurred in Nature, and for this reason looked for it in vegetable extracts. Our belief that oxidising ferments cause glucose metabolism led us to examine vegetables for these ferments and for substances with an insulin-like action. It seems that Collip's theory and ours dovetail. A storehouse of food (glycogen, starch, etc.) and a ferment for the metabolism of this food are necessary wherever growth occurs in vegetables.

Our studies have led us to the tentative suggestion that insulin, which is apparently not itself an oxidase or peroxidase, indirectly stimulates or activates oxidising ferments in the tissue cells to action upon glucose, whereas vegetable extracts contain active oxidising ferments and act directly when injected into animals.

It would seem that the work of Winter and Smith, of Collip, and of ourselves was being carried on simultaneously and independently. Collip, very properly, suggests that "These authors [Winter and Smith] would, therefore, share coincident priority with me in this particular." We think that we should be included in this share of priority.

Scientific Names of Greek Derivation.

Dr. J. W. Evans's letter in Nature (July 7, p. 9) may serve as an excuse for commenting on certain names which have recently been introduced into zoological literature without sufficient regard for etymological principles. Bathosella and Leiosella (Polyzoa) may be given as examples of a series of new genera, proposed in 1917 and later years, with the derivations, as stated, *bathos*, depth, and *leios*, smooth, respectively. In these genera the entire Greek word is used, instead of its root, and the generic name is completed by the addition of a Latin diminutive termination. The suffix *-sella* is in any case likely to cause confusion in Polyzoa, among which *-cella* is the termination of many familiar generic names.

A second series of new genera ending in *-nea* is also of recent introduction, to express an affinity to Idmonea, which was presumably based on ἴδμων. Mesonea and Pleuronea may be mentioned as examples of this misused employment of *-nea*. A third unfortunate suggestion has just been made, to the effect that the Latinised form of ξένος or ξένη (a guest) should be added to the generic name of a host, in forming the trivial name of its parasite. Among the illustrations of this supposed emendation in nomenclature are *ranaxena* and *bufoxena*, both based on Latin words.

According to the Rules of Nomenclature, generic and trivial names cannot be rejected on purely etymological grounds. The same rules do not apply to group-names, and it is accordingly justifiable to suggest that some of them may be amended; for example, that Aplousobranchiata, which has been proposed in Tunicata, should be replaced by the more euphonious name Haplobranchiata.

Dr. W. D. Lang (*Geol. Mag.*, N.S., December, vol. iv., 1917, p. 282) has previously discussed some of the points I have indicated. It may be useful, however, to raise a protest against the continued introduction of names formed in defiance of accepted principles, and I venture to think that this practice will not tend to raise scientific nomenclature in the estimation of scholars.

In 1844 Sir John Herschel wrote to Owen regretting his spelling of the name of the fossil bird Dinornis, and urged that a Frenchman would pronounce the word Denornis, which he would not do had it been spelt Deinornis. To this Owen answered by directing attention to our pronunciation of the word receive.

Herschel does not seem to have retorted, but he might have done so by quoting—

"segnius irritant animos demissa per aurem
quam quae sunt oculis subiecta fidelibus et quae
ipse sibi tradit spectator."

And the retort would have been final.

The Scattering of Light by Anisotropic Molecules.

Prof. L. V. King's interesting letter on this subject in Nature of May 19, p. 667, calls for comment, as his results do not seem to be acceptable in the light of the work carried out at Calcutta in this field during the past two years.

Any proposed scattering formula should satisfy two simple tests, namely, that for a fluid consisting of isotropic molecules it should reduce to the Einstein formula, and that for a sufficiently rarefied fluid it should become the Rayleigh law of scattering. Prof. King's formula (3) satisfies neither of these tests, as can easily be seen on putting $\rho=0$ in it. The appearance of the adiabatic compressibility in the formula is inconsistent with thermodynamic principles. Einstein has very clearly pointed out that the expression for scattering must involve the isothermal and not the adiabatic compressibility. Further, the omission by Prof. King of the factor $(\mu^2+2)^2/9$ which appears in Einstein's formula, cannot be reconciled with the acceptance of the Lorentz refraction formula for a fluid consisting of isotropic molecules.

Prof. King's explanation of the diminution in the depolarisation in the case of liquids, which occurs as the critical temperature is approached, as due to the breaking up of crystalline aggregates, seems inappropriate in view of the fact that a precisely similar effect is shown by vapours, where obviously the conception of crystalline aggregates is entirely out of place. Mr. Ramanathan's paper on the scattering of light in benzene vapour at high temperatures, which is appearing in the *Physical Review*, clearly illustrates this. The effects observed both in liquids and vapours have been very simply explained without recourse to artificial hypotheses in my papers in the *Phil. Mag.* for January and March, where quantitative data strongly supporting Einstein's formulæ are set out.

The fundamental error in Prof. King's reasoning seems to arise at the point where he suggests that a fluid consisting of comparatively stationary anisotropic molecules, with equally probable orientations in all directions, would scatter only polarised light. This is certainly not the case. It can easily be seen on resolving the effect due to an ælotropic molecule oriented arbitrarily that the components perpendicular to the light vector in the incident wave are affected with a sign which may be either positive or negative at random, *i.e.* irrespective of the position of the

molecule in space, and hence, in finding the total components in these directions, we have to add the intensities, not the amplitudes. A fluid consisting of anisotropic molecules oriented at random must therefore necessarily scatter unpolarised light in proportion to its density, and as remarked in my letter in NATURE of March 31, p. 428, considerations similar to those which enter into the Lorentz refraction formula introduce a further factor $(\mu^2+2)^2/9$, which increases the unpolarised scattering to be expected. The whole question will be found elaborately discussed in a paper by Mr. Ramanathan in the Proc. Indian Association for the Cultivation of Science, vol. viii., Part I., just published.

I think I should make it clear that the suggestion made in my letter in NATURE, March 31, and endorsed with some modifications by Sir William Bragg, regarding the relations between the liquid and the crystalline states, is very different from that put forward by Prof. King. In my opinion, neither the facts regarding the scattering of light nor the X-ray data require the assumption of the existence of crystalline aggregates in liquids. All that the experimental facts suggest is that the molecules in a liquid influence the orientations of their nearest neighbours to a sensible extent, and that this results in the amount of unpolarised light scattered being somewhat smaller than on the hypothesis of random orientations of the molecules.

The Doublet Separations of Balmer Lines.

IN his theory of the structure of the lines of the Balmer Series based on the principle of relativity, Sommerfeld shows that each of the members of the series should consist of a doublet and that each of the components of these doublets should possess a fine structure. The calculations show besides that the frequency difference for these doublets should be constant over the whole of the Balmer Series and should be equal to 0·36 cm⁻¹. For H_α the separation should perhaps be slightly less. As the theory applies equally well to the doublets of the corresponding series in the spectrum of positively charged helium, these were investigated by Paschen and were found to have separations that lead to a value of $0{\cdot}3645 \pm 0{\cdot}0045$ for the frequency difference of the doublets of the Balmer Series.

Since the publication of Paschen's work on helium a number of investigators, including the writer, have attempted from the measurements on the separations of H_α and H_β and in some cases of H_γ and H_δ to look for evidence that would lead to a confirmation or rejection of Sommerfeld's theory. Up to the present the results obtained could not be considered as satisfactory. There was a lack of agreement in the values obtained for the separations by different investigators, and on the whole the values obtained were less than that demanded by the theory. In the case of the observations made by myself and Mr. Lowe on the separations of H_γ and H_δ, values were obtained that seemed to point in the direction of a steady decrease in the frequency differences as one passed to the higher members of the series.

At my suggestion the matter was re-investigated recently by one of the research workers in the Physical Laboratory of the University of Toronto, Mr. G. M. Shrum. In his experiments the tubes were of a special design and were cooled with liquid air.

His method of operating these tubes, which will be described later in his own paper, enabled him to eliminate practically the whole of the secondary spectrum and thus permitted him to include in the measurements of the doublet separations that of H_ϵ as well as those of H_α H_β H_γ and H_δ.

The results are the following:

Line.	Wave-length.	Separation of the Components.		Probable Error.
		$\delta\lambda$.	$\delta\nu$.	
H_α	6562·79 Å	0·143 Å	0·33 cm⁻¹	0·02 cm⁻¹
H_β	4861·33 ,,	0·085 ,,	0·36 ,,	0·01 ,,
H_γ	4340·46 ,,	0·070 ,,	0·37 ,,	0·02 ,,
H_δ	4101·73 ,,	0·061 ,,	0·36 ,,	0·02 ,,
H_ϵ	3970·07 ,,	0·055 ,,	0·35 ,,	0·02 ,,

It will be seen that as far as the doublet separations are concerned, they afford a striking confirmation of Sommerfeld's theory.

"Guide to the Mollusca."

WITH reference to the review of the "Guide to the Mollusca" in NATURE of July 21, p. 93, may I be allowed to point out that our rather cautious statement, "A species of *Helix* has been said to tolerate a temperature of −120° C.," was based on Pictet's paper "De l'emploi méthodique des basses températures en biologie" (Arch. Sci. Phys. et Nat. Genève (3) xxx., 1893, pp. 293-314). The reviewer's remark about the scientific names of the pearl mussel and the pearl oyster scarcely makes it clear that we are simply keeping to the names used by the late Mr. E. A. Smith in 1908, *Margaritana margaritifera* for the mussel and *Margaritifera margaritifera* for the oyster. I hope that the other errors he has discovered are not more serious than these.

C. TATE REGAN
(Keeper of Zoology).

British Museum (Natural History),
Cromwell Road, S.W.,
July 23.

MR. REGAN is quite right to direct attention to the fact, which I should have noted, that the confident statement in the text-book concerning the survival of a species of Helix submitted to a temperature of −120° C. had been altered from "has been known" to "has been said," but I still think it would have been better to have omitted it altogether. Pictet in his paper does not say whether the degrees he cites were registered by any one of the more usual thermometers or by a scale of his own (the "C" is an addition in the text-book), and his paper altogether does not suggest that amount of accuracy which the subject demanded. The admission that a system of nomenclature nearly a quarter of a century old has been deliberately adhered to in a work supposedly brought up-to-date, speaks for itself. Much progress has been made in this section of systematic zoology since 1908, and according to all the Rules the pearl oyster (Pinctada) has no right to the name Margaritifera, which belongs to the pearl mussel. There are other examples in the "Guide" of what a malacologist of to-day would call misnaming.

THE REVIEWER.

The Temperatures of the Stars.

By Herbert Dingle.

THE measurement of the temperature of a star is one of the most difficult problems of physical astronomy. The difficulties are of two general kinds. In the first place, the very phrase, "the temperature of a star," has no meaning: we may as well speak of the latitude of the land surface of the earth. There can be no doubt whatever that the temperature varies from one part of a star to another over an enormous range—probably thousands of times greater than the interval between the temperatures of liquid hydrogen and the electric furnace. Secondly, for experimental methods of measurement the only available data are wrapped up in an inconceivably small fraction of the total radiation of the star which reaches the earth after the possible wear and tear of many years' journey through interstellar space and our own atmosphere. From the character of that radiation we have to deduce the temperature of the star. From these two general sources difficulties of many kinds issue forth.

Happily, the resources of modern physics make the problem anything but hopeless. The "temperatures" of a number of stars have been determined by different methods, though exactly what the figures mean, and how much reliance can be placed on them, are perhaps still matters of doubt. With regard to the first source of difficulty, considerable help is received from the spectroscope. More than ninety-nine per cent. of recorded stellar spectra consist of absorption lines on a continuous background—conclusive evidence that a star consists of at least two distinct parts. In the light of Kirchhoff's principle, the continuous spectrum is attributed to the hotter, deeper-lying part, and the absorption lines to a surrounding cooler, but still luminous, atmosphere. Accordingly, temperatures measured from the characteristics of the absorption lines must apply to the atmosphere, and temperatures measured from the continuous spectrum must apply to the interior.

The next questions are evidently: Do the atmosphere and the interior, as thus defined, comprise the whole star, or are there regions outside the one and beneath the other? In the former event, what parts of the atmosphere and the interior have the respective measured temperatures, and, in the latter event, what are the temperatures of the unconsidered regions? For the answers to these questions we are indebted mainly to the nearest star—our sun. We know, from observations made possible by a total solar eclipse, that outside the sun's atmosphere (*i.e.* the source of the absorption spectrum lines) there is the corona—evidently a permanent though ever-changing part of the solar structure. We know also that the source of the sun's continuous spectrum is effectively a layer of limited thickness near the surface, because the luminosity of the sun's disc does not fall off appreciably outwards from the centre until the limb is nearly reached. There must, therefore, be a core inside what we have called the "interior," about which, from direct observation, we know nothing. We may assume, then, that in addition to the regions the temperatures of which we measure from the spectrum of a star, there are other very extensive regions, the temperatures of which it is at present quite impossible to determine by any experimental means.

The temperature throughout the atmosphere of a star may be regarded as a constant quantity. To solar eclipses, again, we owe the knowledge that the sun's atmosphere is very thin compared with the depth of the whole globe. It is true that there are indications that its physical condition varies at different levels, but these variations are refinements of analysis which we cannot hope to apply to the stars for a long time to come. If we can determine a temperature from the absorption lines in the spectrum of a star, we are justified in supposing that we can state definitely the temperature at a particular part of the star. The case is not so clear when we come to the continuous spectrum. We do not know at all definitely from what part of the star the continuous spectrum comes. We know that it must come from beneath the atmosphere, and it has just been pointed out that it represents the radiation of a surface layer, which we may call the "photosphere," but how thick that layer is, and what part of it has the temperature deduced from its spectrum, are questions that are still unanswered.

The first set of difficulties, then, can be partly overcome. Assuming that the sun is a type of its kind, we can divide a star into four distinct parts—a corona, an atmosphere, a photosphere, and a core. Of the temperatures of the first and last, we know, by direct experiment, nothing. The temperature of the second can possibly be measured definitely, and that of the third, vaguely. Supposing these measurements to be made, theory indicates, for certain stars, what must be the temperatures at different parts of the core.

Turning now to the second set of difficulties—those connected with the actual measurement of the temperatures—we note that these may be subdivided into the difficulties of obtaining the requisite data, and those of interpreting the data when they are obtained. It is probably fair to say that, in measuring atmospheric temperatures, the former preponderate, while the latter are most in evidence in the measurement of photospheric temperatures. It was Lockyer who first showed the influence of temperature on the line spectrum of a substance, and urged that the relative temperatures of stellar atmospheres could be determined from a study of the lines by which particular substances were represented. More recent investigations, originated by Saha, have confirmed Lockyer's views, and have shown how the actual temperatures can be calculated. But it appears that, while temperature is probably the chief factor in determining the line spectrum, it is by no means the only one. Pressure, the absorption of photospheric radiation, the relative amounts of different substances in the atmosphere, the ionisation potentials of the elements—these at least play a part, and must be determined before the temperatures can be found. Unfortunately, they are, in most instances, unknown, and their values have to be assumed, on more or less plausible grounds. There is, therefore, a considerable element of uncertainty in existing estimates of the temperatures of stellar atmospheres.

The temperatures of the photospheres are deduced from the distribution of energy in the continuous spectra. Laboratory experiments on black-body radiation show that the spectrum of a perfect radiator at uniform temperature is characteristic of the temperature. Wien's displacement law states that the wave-length of the radiation carrying the maximum amount of energy is inversely proportional to the absolute temperature of the source of radiation, and Planck's radiation formula expresses, with great accuracy, the distribution of energy throughout the spectrum. Assuming that the photosphere of a star bears the same relation to its continuous spectrum as does the equivalent of a black body in the laboratory, the photospheric temperatures are found. Wilsing and Scheiner, of Potsdam, and Nordmann, of Paris, have used the method, and Sampson has recently shown that, by employing a photo-electric cell as an energy detector, the accuracy of the measurements may be greatly increased.

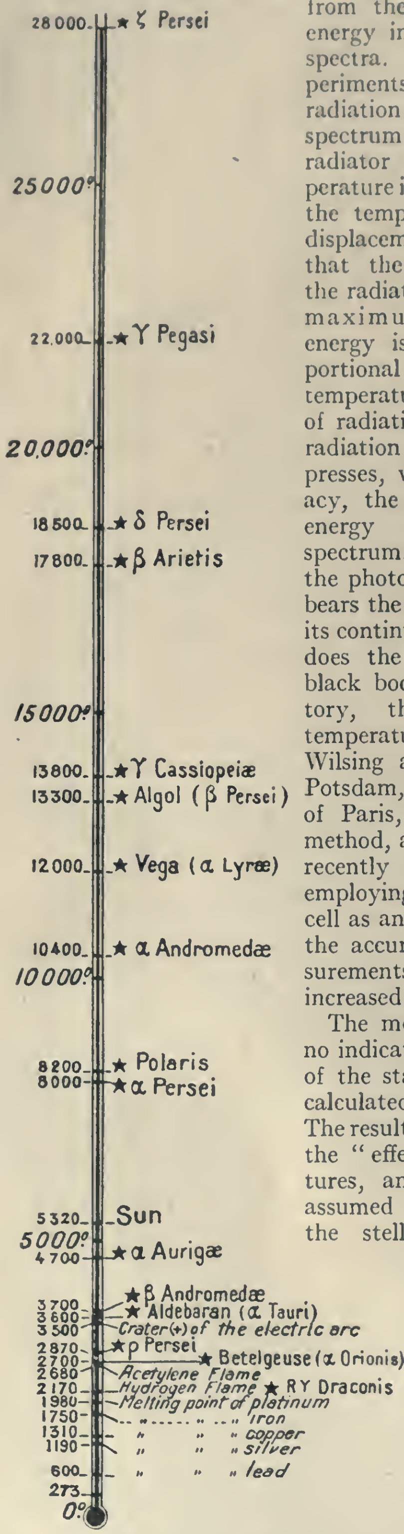

Fig. 1.—Scale showing, in absolute centigrade degrees, the temperatures attained in certain terrestrial processes compared with the effective temperatures of representative stars.

The measurements give no indication of the region of the star which has the calculated temperature. The results are spoken of as the "effective" temperatures, and are generally assumed to characterise the stellar surfaces, immediately beneath the atmospheres. Two remarks might be made concerning them. First,—granting for a moment the validity of the method of measurement, they represent minimum temperatures only, for if the stars are not perfect radiators, their temperatures must be higher than the calculated ones. Second,—it is a somewhat dangerous assumption that the resultant radiation from a globe of gas, perhaps millions of miles in depth and varying in almost every physical quality from point to point, will give a spectrum comparable with that of a thin solid surface at a uniform and probably very much lower temperature. We know practically nothing as yet of the processes of production of continuous spectra. We have no means of distinguishing one such spectrum from another except by measuring the distribution of energy in it; yet it is certain that there may be profound differences in the modes of origin. The continuous spectra of a cold fluorescent body, of an electric glow-lamp, of hydrogen radiating also the Balmer series—here at least are three spectra which probably have nothing in common except their appearance. The stellar nuclei of planetary nebulae, again, give spectra which suggest the operation of the classical laws of radiation rather than those of the quantum theory, unless the stars have temperatures so high that no one is prepared to accept them.

It is noteworthy, however, that the atmospheric and photospheric temperatures, estimated by totally different, and at best approximate, methods, are of the same order of magnitude. Fig. 1 [1] shows, on a thermometric scale, the range of temperatures covered by present measurements. Temperatures have been measured at almost all points intermediate between the absolute zero and the temperature of ζ Persei. The cores of the stars, according to Eddington's theoretical researches, reach temperatures far too high to appear on the scale. It is probable that there are bodies in the universe at all temperatures between absolute zero and 20 million degrees centigrade or higher.

Whatever may be said of the absolute accuracy of stellar temperature measurements, it is scarcely questionable that they show the true order in which the temperatures are arranged. There is no doubt whatever that Vega is hotter than Aldebaran in corresponding regions. Consequently, if the order of stellar evolution can be established from other data, it becomes possible to determine the changes of temperature of a star throughout its life. Russell's well-known theory of evolution takes the order of increasing density of a star to be its order of development: contraction is a continuous process from childhood to old age. This implies that a star passes twice through the same series of spectral types, and therefore through the same series of temperatures. Beginning as a huge, rarefied, cool mass of gas, it contracts and becomes hotter until a stage is reached when it is too dense to obey the laws of a perfect gas. The temperature then soon reaches a maximum and begins to fall—contraction, however, continuing, though at a slower pace—and the star retraces its path through the sequence of spectral types which it traversed on its upward journey. While the temperature is rising, the star is a "giant," and after it begins to fall the star becomes a "dwarf." The career of a typical star, with time as abscissa and temperature as ordinate, is pictured in Fig. 2: continuous contraction is indicated by the decreasing diameter of the circles representing the star.

[1] The diagrams illustrating this article are adapted, by kind permission of Dr. Charles Nordmann, from an article by him on "La vie et la mort des étoiles," which appeared in *L'Illustration* of April 7, 1923.

The temperature reached at the maximum point depends on the mass of the star: the greater the mass, the higher the temperature and the longer the stellar life. Fig. 3 illustrates the careers of the sun and of stars the masses of which have nearly the extreme values found in Nature. Probably a star having a mass less than one-tenth of that of the sun would not become hot enough to be seen, while Eddington has shown that stars much more than ten times as massive as the sun would be unstable. Only the most massive stars can reach the B and Oe 5 stages of the Harvard spectral sequence. The lighter stars, like the sun, turn back at the A condition, or even at a still lower stage.

Temperature appeared at first, in this great stellar drama, to play a dependent rôle. The star developed heat by contraction, and radiated heat into space. So long as the amount of heat developed exceeded the amount radiated, the temperature would rise, and when, through retardation of contraction and increase of radiation, the conditions were reversed, the temperature would fall. This view is satisfactory in every respect but one—it indicates a length of stellar life far shorter than geological and other evidence makes it possible to admit. In order to account for the amount of heat which a star radiates during its immeasurably long life, it is necessary to suppose that the heat generated by contraction is supplemented by an enormous supply of energy from some other source. Nothing is certainly known of the nature of this supply. Possibly, as Eddington proposes, it is to be found in the formation of heavier elements from hydrogen. But, wherever the energy comes from, it is difficult to avoid the hypothesis that it can be released only at the extremely high temperatures attained near the centres of stars. Contraction raises the temperature of a star up to a certain point, and then temperature takes charge and sets free energy from the unknown source at a rate almost equal to the rate of radiation, so that the star is in a condition of approximate equilibrium. It is a problem for the future to determine the origin of the almost inexhaustible supply.

FIG. 2.—Diagrammatic representation of the theoretical development of a massive star from an original nebula to a final cold, dense body. The dotted curve is to be regarded as identical with the highest curve in Fig. 3.

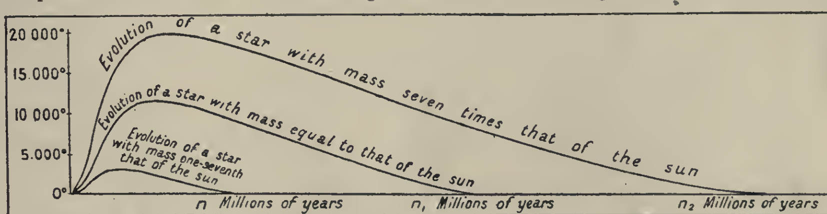

FIG. 3.—Curves illustrating the course of evolution of stars of differing mass, showing that, the more massive the star, the longer is its life and the greater is the range of temperature through which it passes.

Man and Scottish Animal Life.[1]

By Dr. JAMES RITCHIE.

IN the opportunity it affords for the study of the part man plays in the evolution of a fauna, the animal life of Scotland stands alone. This is largely due to a series of geological accidents: the Glacial Period, which made a clean sweep of former faunas; the post-glacial continental land bridge, which allowed immigration from the mainland of Europe, and the subsequent breaking of the continental connexion. Thus there was isolated on the *tabula rasa* of Scotland a fair sample of the post-glacial European fauna, which henceforth was removed from the possibility of subsequent migrations such as complicate the history of continental faunas, and the later evolution of which must in general be due either to the influence of physical and organic changes limited in time and space, or to the interference of man.

The influence of man was itself strictly limited in time, for the earliest human settlements so far recognised in Scotland date back only to Azilian times. It was also unequal in its incidence, gaining in intensity with the passing of time. Thus during the Neolithic, Bronze, and early Iron Ages only some four of the larger members of the original fauna disappeared—the giant fallow deer, the lynx, the lemming, and the rat vole—and it is doubtful whether the disappearance of any of these was due to man's presence. We may say, therefore, that when the Roman legions followed Agricola northwards through the marshes of Scotland in the early years of our era, they found a fauna which, except for the presence of primitive domesticated animals, differed little in kind from that which greeted man on his first arrival in Scotland some 8000 years before. But the following centuries saw more rapid changes, which so increased that by the sixteenth century many new and important elements had been added, while most of the larger members of the old fauna had been swept away, with the extermination of such as the reindeer, the elk and the wild boar, the brown bear and the beaver, the great bustard, the crane and the bittern. Nowadays the content and assortment of the fauna, the relative numbers of its members and their distribution, show little resemblance to the conditions of the original post-glacial immigrants.

The degree of man's interference may be compared

[1] Summary of an address delivered at the request of the Council to the Royal Society of Edinburgh on July 2.

with the influence of the ordinary forces of Nature which are constantly modifying the animal life of a country. There is a constant ebb and flow within a fauna, a swing of numbers due largely to seasonal changes and fluctuating about a mean—the "balance of life"; and where man's interference is temporary in its incidence it falls into this category. But there is, besides, a definite faunal evolution, a faunal drift; and where man's influence is persistent in one direction it must be reckoned as sharing with the great secular forces of Nature in propelling a fauna upon a path along which there is no return.

The nature of man's interference, directly or indirectly exercised upon the animal life of Scotland, is of great complexity, but it may be conveniently grouped according to results. In some ways man has reduced the numbers of animals, in some ways he has increased their numbers, and in some ways he has modified their habits and even their structures. Reduction of the fauna, which, commencing with a mere cutting off of the numbers of a species, may proceed to a marked limitation in the range of distribution and finally to extinction, has been brought about directly by deliberate destruction, as in the cases of the polecat and the urus, and indirectly by cultivation, which has destroyed feeding grounds and breeding haunts, driving away such as the great bustard and the bittern, as well as by destruction of the forest. with which disappeared the capercaillie and the red squirrel, both since reintroduced. Increase in the quantity of the fauna is largely due to an intensive cultivation which has provided bounteous food-supplies for such as rabbits and sparrows, and to deliberate protection of other creatures for food, sport, or amenity. The quality of the fauna has been increased by the addition of new elements from other lands, either introduced deliberately, like pheasants and the common rabbit, or carried hither by mischance of international commerce, like the black and brown rats and many an insect pest. Habits have been changed: the one-time cliff-dwelling swallow has been converted into an inhabitant of houses; and structures have been changed in converting wild into domesticated animals, and by the alteration of habitats, whereby the red deer has lost many points from its antlers and several cubits from its stature.

It must not be imagined, however, that a simple enumeration of first effects exhausts the tale of man's interference. The story of the effect produced, by protecting a few black-headed gulls, upon the vegetation of a heather moor and its fauna (which I have described elsewhere) illustrates how the slightest interference with wild life may produce complicated and far-reaching results, and that in a remarkably short space of time.

A final comparison of the modern fauna of Scotland with that found by Azilian man on his arrival on these shores, shows that the modern fauna is much more rich in numbers than the old fauna, and that in addition, in spite of the extermination of many forms, it is also more varied in species. The consistent tendency throughout the period of man's presence has been for the larger animals, which formed the most impressive contingent of the wild life, gradually to be rooted out; while the additions consist largely of lesser creatures, many of which have gained entry only because their minuteness has enabled them to escape detection. The great change therefore has been a notable diminution in the standard of size of the wild fauna, and this tendency is still strongly marked in the evolution of the Scottish fauna at the present day.

Obituary.

Mr. S. S. Hough, F.R.S.

Mr. Sydney Samuel Hough, H.M. Astronomer at the Royal Observatory, Cape of Good Hope, died on Sunday, July 8, at Gerrard's Cross. He had visited Europe last summer and had attended the meeting of the International Astronomical Union at Rome, but after his return to South Africa he was in poor health and ultimately cancer was diagnosed. He came back to England under the care of a nurse in the spring of this year and succumbed to the disease after a painful illness.

Mr. Hough was born at Stoke Newington on June 11, 1870. After distinguishing himself at Christ's Hospital School, he proceeded to St. John's College, Cambridge, as a foundation scholar. At Cambridge he had a brilliant career and graduated as third wrangler in 1892. He was awarded the first Smith's prize in 1894, and soon after was elected to an Isaac Newton studentship and to a fellowship at his college.

After taking his degree, Mr. Hough devoted himself to research work in astronomy and geophysics. It had recently been found by Küstner and Chandler that the free period of the variation of latitude differed from that predicted by Euler, and the investigation of this subject was undertaken by Mr. Hough. He passed on under the guidance of Sir George Darwin to an investigation of the tides on dynamical principles, and succeeded in deriving a more complete solution of the tidal problem than had been previously obtained, and indeed in making the most important contribution to this theory since Laplace. In his work he introduced the mutual gravitation of the water, and he determined the periods of free oscillation of the ocean. At this time he also did some work on periodic orbits.

When Mr. Finlay, chief assistant at the Cape Observatory, retired in 1898, Sir David Gill, who was then H.M. Astronomer, pointed out to the Admiralty the importance of selecting as his successor a man with the highest scientific qualifications who might be expected ultimately to become director of the observatory. In accordance with this plan Mr. Hough was selected for the post and he proceeded at once to take up his duties. He became H.M. Astronomer in 1907.

Mr. Hough threw himself into the work of the observatory and made valuable contributions to astronomy in organising and discussing observations, particularly those relating to the exact positions of the stars. This work is of a kind which does not attract much public notice, but it is absolutely fundamental to astronomy. Soon after his arrival at the Cape he was entrusted with the reduction of a triangulation of close circumpolar stars made with the

heliometer. These observations were carefully discussed for systematic errors and combined with meridian and photographic observations so as to give accurate positions of all the brighter stars in this region. The subject of the accurate positions of southern circumpolar stars engaged Mr. Hough's attention to the end, and four parts of Vol. XI. of the Cape Annals deal with these stars.

Mr. Hough's chief work was done with the new Cape Reversible Transit-Circle. This instrument is probably the best of its kind in existence and was designed by Gill with a view of the elimination of all conceivable sources of error. The principal parts of the instrument arrived at the Cape in 1901, but a considerable time naturally elapsed before it was ready for use with its collimators and underground azimuth marks in position. In 1903 and 1904 Mr. Hough spent a large part of his time in the determination of the constants of the instrument, in particular the error of every one of the 5′ divisions of the fixed circle was determined. The new transit circle was brought into regular use in 1905. Under Mr. Hough's direction two catalogues of fundamental stars based on observations for the years 1905–11 and 1912–16, containing respectively 1293 and 1846 stars, have been published. Each star has been observed at least sixteen times, four times in each of the four positions of the instrument, and the resulting star places must be among the most accurate we have.

Under Mr. Hough's direction, rapid progress has been made in the completion of the Cape Astrographic Catalogue, Declination 40° to 52° South. Five volumes of measures have now been issued, and this year a magnificent volume giving the spherical co-ordinates of all stars down to and including the 9th magnitude of the C.P.D. scale. There are in all 20,843 stars in this catalogue, and the places have been deduced from all the material available both from the meridian observations and the photographic plates. The overlapping parts of the plates have been carefully compared and the plate constants adjusted so as to give the best agreement possible. This volume has entailed a large amount of work and must prove of the greatest value in the future.

It is impossible to enter here at length into the different phases of Mr. Hough's work. The meridian observations of the inner planets and the heliometer observations of the outer planets have been carefully collected and discussed. In conjunction with Mr. Halm he discussed the motions of the Bradley stars, and he has derived an accurate value of the solar parallax from the radial velocities of stars as observed at different seasons of the year. Besides giving observations of the greatest accuracy the Cape Publications contain valuable discussions for the derivation of the fundamental constants of astronomy.

Mr. Hough's contributions to astronomy were recognised in various ways. In 1902 he was elected F.R.S. He was president of the South African Philosophical Society in 1907, and on the reconstruction of that society as the Royal Society of South Africa he was elected its first president. Last year he was elected British vice-president of the International Astronomical Union. His death at the age of fifty-three is deeply felt by astronomers throughout the world.

J. J.

SIR HENRY H. HOWORTH, K.C.I.E., F.R.S.

BY the death of Sir Henry Hoyle Howorth on July 15, at the age of eighty-one, scientific circles lose a characteristic figure belonging to a generation which has almost passed away, while his many friends mourn the loss of one for whose qualities all had an intense respect and admiration. A man of strong individual character, he had foibles which he himself was not the last to regard with some humour. His most remarkable characteristic, however, was his wide intellectual range and the vast, and sometimes surprising, extent of his knowledge. A constant attendant at the meetings of many scientific societies, there were few subjects on which he was not prepared at a moment's notice to make a real contribution to discussion.

Born in Lisbon on July 1, 1842, Howorth was educated at Rossall School and called to the Bar by the Inner Temple in 1867. He soon, however, turned his attention to politics and historical and archæological studies, which became his main interests in life. Of the large number of scientific and historical works on a variety of topics which he published, the first were two papers dealing with the races of Northern Russia and the extinction of the mammoth respectively, which were presented to the British Association in 1868 and 1869. They were followed by a number of papers published in rapid succession in the journals of scientific societies such as the Royal Anthropological Institute, the Royal Historical Society, the Royal Asiatic Society, and the like. They dealt, among other subjects, with the ethnology and history of the peoples of Central Asia and Eastern and Central Europe and with geological topics connected with the polar areas, and may be regarded as preliminary studies for the works with which his name will mainly be associated in the future. Of these, one, his "History of the Mongols," of which the first volume, dealing with the Kalmucks and Eastern Mongols, was published in 1876, the second, dealing with the Tartars, in 1880, and the third, on the Mongols of Persia, in 1888, brought him recognition in the form of the K.C.I.E. in 1892 and election to the fellowship of the Royal Society in the following year. He also published a "History of Chengis Khan and his Ancestors" in the *Indian Antiquary*. He had begun to rewrite his "History of the Mongols"; but the revision was incomplete when he died.

For the ordinary individual these detailed studies of Asiatic history and ethnology might well have sufficed; but they were not adequate to satisfy the needs of an intellectual energy so indefatigable as that of Howorth. He took up the study of glacial problems with equal zeal, and, be it said, with his usual love of controversy. "The Mammoth and the Flood" appeared in 1887, and "The Glacial Nightmare" in 1893, both being parts of a vigorous attack on Lyell's glacial theory, based upon palæontological, geological, and archæological evidence and suggesting that the deposition of drift and boulders was due to wave, rather than glacial, action. He followed this up with "Ice or Water?" which appeared in 1905. At the time of his death he was engaged on the revision of "The Mammoth and the Flood."

Sir Henry was also keenly interested in the history of the Church, and was the author of a valuable and

authoritative study of St. Gregory the Great, which was followed by "Augustine the Missionary." He also wrote "The Golden Days of the Early English Church," published in 1916, and edited a "History of the Vicars of Rochdale" for the Chetham Society.

It is surprising that, amid all this literary and scientific activity, Sir Henry should have been able to devote so much time to politics and public affairs, on which he was a frequent and voluminous writer in the correspondence columns of the Press. He was elected member of Parliament for South Salford in 1886, 1892, and 1895. In 1902 he did not seek re-election. Although he sat as a Unionist, he adopted an independent attitude, giving a free rein to powers of criticism and controversy which lost nothing by his command of language.

In addition to the honours already mentioned, Sir Henry Howorth was an honorary D.C.L. of Durham University, a trustee and honorary librarian of Chetham College, and, from 1899, a trustee of the British Museum. He had been president of the Royal Archæological Institute and the Viking Society, and was a vice-president of the Royal Asiatic and of the Royal Numismatic Societies.

Dr. Louis Bell.

Dr. Louis Bell died at his home at West Newton, Mass., on June 14. He was born in Chester, New Hampshire, in 1864, and twenty years afterwards graduated at Dartmouth College. He then specialised in physics and applied engineering, receiving the Ph.D. degree from Johns Hopkins University in 1888. In the same year he was elected professor of physics at Purdue University, Lafayette, Ind. He edited the *Electrical World* from 1890 to 1892, and was then appointed Chief Engineer of the power transmission department of the General Electric Company. In this capacity he installed at Redlands, California, the first three phase transmission plant which was used for general service. From 1895 to 1905 he lectured on power transmission to the Massachusetts Institute of Technology, while for twenty-seven years he was a consulting engineer in Boston.

Dr. Bell did excellent pioneering work on illuminating engineering and on power transmission. His "Electric Power Transmission," published in 1897, was for several years the standard textbook on the subject. For many years also his "Art of Illumination," published in 1902, was the standard work on illuminating engineering. He contributed articles on "Electrical Power Transmission" and on "Electric Motors" to the 10th and 11th editions of the "Encyclopædia Britannica," and published many technical articles chiefly on alternating currents, electric traction, illumination, physiological optics and radio-telephony. He was a manager of the American Institute of Electrical Engineers from 1891 to 1894 and was a past president of the American Illuminating Engineering Society. His work on photometry for the International Electrical Commission was much appreciated by engineers all over the world.

The former Director-General of the German Continental Gas Co., Dr. W. v. Oechelhaeuser, died on May 31, at Dessau (Anhalt). He was born on January 5, 1850, at Frankfort-on-Main. He studied engineering science at the Technical High School in Berlin, made rather extensive journeys in foreign countries and entered in 1887 into the services of the German Continental Gas Co. at Dessau, of which firm he was Director-General during the years 1890–1912. His technical achievements, based upon sound scientific knowledge, have been acknowledged by the bestowal of the honorary degrees of Dr.Ing. and Dr.Phil. Dr. von Oechelhaeuser contributed largely to the development of the gas industry; for example, he substituted for the old type of horizontal gas retorts, with their great amount of hand work, the vertical retorts, in which the coal glides down by its own weight and at the same time is gasified. On the other hand, he constructed the first engine on the Oechelhaeuser system, by which it became possible to use the gas from a blast furnace directly for power production. In addition to this, he was successful in raising the social standing of the engineer in Germany, in his capacity of president, during many years, of the Society of Gas and Water Engineers and of the Society of German Engineers.

Prof. Hermann Scholl, professor of technical physics of the University of Leipzig, died on June 27, aged fifty-one. His premature death will be much regretted. He was born on January 14, 1872, in Eupen, Rhenish Prussia, and studied at the Technical High School, Aix-la-Chapelle, and at the University of Giessen, where he became assistant to Prof. Otto Wiener, with whom he moved to Leipzig in the year 1899. In 1910 he was made professor of technical physics, and he organised the practical courses of this study at the university. His investigations were concerned mainly with the relation between light and electricity; for example, he was of opinion that electric action of the light plays an important part in the first-known photographic process, the daguerreotype process. Much important work was done by Scholl in his capacity as an expert of the Reichsgericht in patent cases. In numerous decisions concerning the validity of patents connected with electricity and mechanics, the senate of the supreme German court of justice followed Scholl's opinion. In consequence of his far-reaching scientific knowledge and thorough understanding of technical questions, Scholl exerted great influence upon the development of industry. Industrial circles, as well as his colleagues and pupils, will be much afflicted by the loss of this distinguished man.

We regret to announce the following deaths:

Dr. E. Beckmann, on July 12, aged seventy. An appreciative note on his life and work appeared in our issue of July 21, p. 109, when the occasion of his seventieth birthday celebrated on July 4 was recorded.

Prof. L. Hiltner, president of the Bavarian Botanical Institute, on June 6.

Prof. E. W. D. Holway, of the University of Minnesota, known for his work on the rust-fungi, on March 31, aged seventy.

Prof. F. Krafft, professor of chemistry at Heidelberg, aged seventy-one.

Dr. Josef Nevinny, professor of pharmacology and pharmacognosy at the University of Innsbruck, aged seventy.

Prof. J. P. Langlois, of the Conservatoire national des Arts et Metiers, and editor since 1910 of the *Revue générale des Sciences*, on June 17.

Dr. J. G. Rutherford, chairman of the International Commission on Control of Bovine Tuberculosis and Canadian delegate at the International Institute of Agriculture at Rome in 1908, on July 24, aged sixty-five.

Current Topics and Events.

The problems of physics are manifold, and tend to increase in number and in difficulty. Fifty years ago there was a general feeling that we had only to proceed steadily in the application of familiar dynamical principles to explain all the phenomena of inanimate nature. Some men of science would have included in such an explanation the facts of animate nature as well. How different is the position to-day! Sir Oliver Lodge, in the illuminating address which appears as a supplement to this issue, expounds the difficulties and perplexities which now face the natural philosopher, summing them up in the two words, "ether" and "electrons." The relativist may, for his own special purposes, ignore the ether, but Sir Oliver claims that as we find ourselves imbedded in ether and matter, it is necessary to take stock of our position and consider how much it is possible to ascertain as to etherial properties. The outstanding problems of our time, that of radiation on one hand and of atomic structure on the other, have been at least partially solved by the electro-magnetic theory of Clerk Maxwell and the electron theory which owes so much to his successors at the Cavendish Laboratory. But the still greater problem of relating these theories satisfactorily to one another and to the disquieting results embodied in the modern theories of quanta and relativity still awaits the revealing power of the master mind. The acceleration of an electron generates waves. In photo-electricity we find that radiation can fling out an electron with a surprising amount of energy. There is thus a remarkable reciprocal relation between light and electrons. With characteristic boldness Sir Oliver Lodge tackles the relations between radiation and matter and suggests—in the form of a question, it is true—that the actual generation of an electron by means of light is not an altogether impossible idea. The suggestion is perhaps not entirely new, but it has never been stated with such clearness and force, and deserves the serious consideration of scientific thinkers.

It is a remarkable fact that, despite the immense advances in our knowledge of bacteria as the causative factors of infective disease, the viruses of the eminently contagious exanthematic diseases have not been unmasked. The causes of measles, scarlet fever, small-pox, chicken-pox, and typhus have not been found with certainty. Naturally, a great many researches have been carried out to discover these unknown causes, and in the earlier days of bacteriology many micro-organisms were incriminated which are now known to be accidental contaminations or are accessory to the main cause. The history of investigation on scarlet fever illustrates this admirably. Cocci of diverse kinds, bacilli, and even protozoa, have been alleged to cause the disease. The most recent report comes from Italy, where it is alleged that di Cristina of Palermo and Carolia of Rome have discovered the germ of scarlet fever in the form of an ovoid diplococcus. From what we know of bacteria in disease, it is improbable that the exanthemata are due to microbes of this class. The contagiosity, the eruption, and the high degree of immunity point to a special class of diseases differing altogether from the bacterial infective processes. Hektoen (1923) has recently published an interesting historical research detailing the various attempts which have been made to transfer scarlet fever intentionally to man, and he considers it very doubtful whether this has ever taken place. This is remarkable when one considers the ease with which the disease is transmitted under natural conditions.

The Rothamsted Experimental Station is one of the Institutions to which the Empire Cotton Growing Corporation has made a grant of 1000*l.* for five years, for the development of research work likely to be of importance in relation to problems connected with cotton-growing. It is evidence of the enlightened outlook of the Corporation to research that the grant is free from any restrictions likely to hamper the progress of the work. The money will be employed in increasing the staff and equipment of the Soil Physics Department, in order that more rapid progress may be made in the study of the fundamental physical properties of soil. Special attention will be devoted to the water relationships, in view of their importance in districts where cotton is grown. The elucidation of these principles is necessary before trustworthy advice can be given to the growers, and, conversely, the practical problems that the local experts are expected to solve often present points that can only be answered after investigations in a research laboratory under controlled conditions. The function of the Soil Physics Department at Rothamsted will be to undertake these investigations as part of its study of the fundamental properties of soil. The Department will act as the headquarters of those men on study-leave who wish to discuss soil problems arising in the course of their work, and they will be provided with facilities for experimental investigations.

The Polish Physical Society was founded in April 1920, with five branch sections in Warsaw, Cracow, Lwów, Wilno, and Poznań respectively. Prof. Ladislas Natanson, of the Jagellonian University of Cracow, was the first president of the Society for the period 1920–23, and in the general assembly held in Warsaw in April last Prof. St. Pieńkowski was elected president and Prof. Natanson vice-president. The first part of the Society's Transactions, referring to the period 1920–21, has been recently issued. It is an interesting volume containing a number of important contributions. There is an obituary notice of Prof. Tad. Godlewski; Prof. Natanson's presidential address; and a number of papers: on the diffusion and scattering of light, especially in water, by Prof. Cz. Bialobrzeski; on discharge in electrodeless tubes, by Prof. J. Wierusz-Kowalski; on the spectra of iodine vapour, by Mr. Landau-Ziemecki; on the magnetic anomalies in Poland, by Prof. St. Kalinowski; on the electrometric study of radioactive fluctuations, by Messrs. Wertenstein and

Muszkat; on the equilibrium of a radiating gaseous sphere, by Mr. W. Pogorzelski. The original text is in Polish; there is, however, a French translation or résumé of every item. The Society has about 120 members, and its address is 69 Hoza Street, Warsaw, Poland. By strenuous and careful work, the Society should do much to promote the progress of physical science in Poland.

On September 17-30, the American Association for the Advancement of Science will meet at Los Angeles with the Pacific and South-western Divisions, and a number of other societies are also gathering at the same place. The path of totality of the total eclipse of the sun on September 10 passes close by Los Angeles, so many distinguished astronomers who have journeyed to the neighbourhood for observing the eclipse are expected at the meeting. According to *Science*, Section D (Astronomy) is to hold joint meetings with the American Astronomical Society and the Astronomical Society of the Pacific at the University of Southern California, at the Mount Wilson Observatory and at the California Institute of Technology. A symposium on "Eclipses and Relativity," at which Dr. W. W. Campbell, president of the University of California, Dr. C. E. St. John, of Mount Wilson Observatory, and Dr. S. A. Mitchell, of the University of Virginia, are to deliver addresses, has been arranged for the opening day of the meeting.

"Æolus," on whose letters in the *Wimbledon Borough News* we commented in our issue of June 30, p. 889, has addressed to us a further letter in which he renews his protest against the by-pass road planned alongside Beverley Brook, and bespeaks our sympathy for the human users of Wimbledon Common no less than for the other animals. Unless the whole of the Fitzgeorge estate is bought for the public (a somewhat hopeless hypothesis), there will be roads of some kind, and we are not aware of any scheme better than that which was reached by representatives of the varied interests concerned. It has, we understand, been proposed that a belt of trees shall be planted to screen the road, a practicable measure which has our full support. No excessive stream of motor cars is anticipated, and indeed our own experience of Wimbledon Common is that small boys and the scatterers of paper are more destructive of its natural peace and beauty than is any of the high-road traffic.

It is curious how often scientific announcements made in British journals are overlooked by the general Press at home, but appear later as messages "From our own Correspondent" abroad. An example of this is a message from the New York correspondent of the *Times*, published in the issue of July 30, upon the discovery, by Prof. J. B. Collip, of an insulin-like plant hormone to which he gave the name "Glucokinin." The discovery was described by Prof. Collip in Nature of April 28, p. 571. It seemed scarcely worth while, therefore, to cable from New York that it "was announced here yesterday by Prof. J. J. Wiltman, of the University of Minnesota, through the American Chemical Society," especially as Prof. Collip's own letter of three months ago provided much fuller information.

Mr. Alec Ogilvie has been elected chairman of the Royal Aeronautical Society for the year 1923–1924, in succession to Prof. L. Bairstow.

The Secretary of State for the Colonies has appointed Lieut. J. R. Stenhouse to be master of the research ship *Discovery*, which, as announced in Nature of April 21, p. 540, is to proceed to the neighbourhood of South Georgia and the South Shetlands in order to obtain scientific evidence bearing on the whaling problem.

With reference to a note in Nature (July 7, p. 19) on the work in archæology of the late Prince of Monaco, Mr. F. Fawcett writes that while the excavation of the caves and the collection of the relics are due to the Prince, the building in which they are stored was constructed through the liberality of the late Sir Thomas Hanbury of La Mortola.

The Department of Scientific and Industrial Research requires a research engineer to take charge of the Building Research Board's Experimental Station, East Acton. Candidates should be honours graduates in civil engineering, or possess equivalent qualifications, and if possible have had experience in research in building materials and construction. Applications, with testimonials, etc., must be made in writing by, at latest, August 20, to the Secretary, Department of Scientific and Industrial Research, 16 Old Queen Street, S.W.1.

Applications are invited for the Yarrow scholarships in connexion with the Institution of Civil Engineers. The scholarships vary in value from 50*l.* to 100*l.* per annum and are open to British subjects who, desiring to become engineers, lack sufficient means to enable them to pursue their practical or scientific training. The regulations concerning the scholarships are obtainable from the Secretary of the Institution of Civil Engineers, Great George Street, Westminster, S.W.1. The latest date for the receipt of applications is September 30.

The following awards have been made by the Royal College of Physicians: The Baly gold medal, given every alternate year to the person who shall be deemed to have most distinguished himself in the science of physiology during the two years immediately preceding the award, to Mr. J. Barcroft; the Bisset-Hawkins medal, bestowed triennially on some duly qualified practitioner, who is a British subject, and who has, during the preceding ten years, done such work in advancing sanitary science or in promoting public health as, in the opinion of the College, deserves special recognition, to Dr. T. M. Legge. The Harveian Oration on St. Luke's Day will be delivered by Prof. E. H. Starling.

In connexion with the visit of members of the Society of Glass Technology to France, during the first week of July, two meetings with French glass

manufacturers were held on Monday, July 2. In the morning the visiting party was received by the Chambre Syndicale des Maîtres Verreries, and was welcomed by its president, M. L. Houdaille, who described to the visitors how the French glass manufacturers are all united in one body—the Chambre Syndicale—which is divided into six sections representing various branches of the industry. The work of these sections is organised in such a way as to prevent ruinous competition between members, and at the same time encourages individual research and development. In the afternoon a joint meeting was held with the Société des Ingénieurs Civils, in the course of which the following papers were presented: "La Méthode Scientifique dans l'Industrie," by Prof. H. Le Chatelier; "Les Verres, Opaques et Colorés, et les Glacures Céramiques de Même Espèce," by Dr. A. Granger; "La Dilatation des Verres et Cristaux," by M. Lafon; "Specifications for Glass Products," by Prof. W. E. S. Turner; "Improvements in the Design of Recuperative Glass Pot Furnaces," by Mr. T. Teisen; and "The Physical Properties of Boric Oxide Glasses," by Mr. S. English and Prof. W. E. S. Turner. During the week, visits were paid to glass works at St. Denis, Rheims, Chantereine, St. Gobain, Chauny, and Cirey. A visit was also paid to the sand quarries at Nemours and to the forest and castle of Fontainebleau. Altogether, some thirty British members of the Society and their friends took part in the visit. Encouraged by the success of this and the visit in 1920 to America, it is proposed to arrange other tours as opportunity arises.

A MEMORANDUM regarding the probable amount of monsoon rainfall in 1923 was submitted, in the early part of June, to the Government of India by Mr. J. H. Field, officiating Director-General of Observatories. For the purpose of a forecast of the monsoon, India is divided into five sections, and the several conditions which are favourable for the various sections are given—the conditions ranging over a large part of the globe, and at different seasons of the year. It is noted that a marked feature of the weather in May was the comparative absence of temporary advances of the monsoon in the Arabian Sea, where the monsoon proper was behind time. Details are given of the influencing conditions in different parts of the globe, and from these it is concluded that there would be some delay in the establishment of normal monsoon conditions within the Indian area, but it was estimated that the delay was not likely to be prolonged. With regard to the total amount of monsoon rainfall, it seemed that in the Peninsula there should be a small excess, with a corresponding excess in Mysore and Malabar. For northern India and Burma no forecast could be issued. Recent telegraphic communications from Bombay received in the middle and towards the end of July state that the agricultural outlook is now satisfactory over almost the whole of the Bombay Presidency, where enough or more than enough rain has fallen nearly everywhere. According to usual custom a further monsoon forecast will be issued in August; past experience shows that the earlier forecast issued in June is usually on the whole the more successful.

A MURAL tablet to the memory of the great naturalists and lifelong friends—Frederick Du Cane Godman and Osbert Salvin—was unveiled at the Natural History Museum on July 28 by Lord Rothschild, and was accepted by the Archbishop of Canterbury on behalf of the Trustees of the British Museum. Upon the death in 1919 of Godman, who was for many years a Trustee and a generous benefactor to the Museum, a Committee was set up with the object of placing in the building a memorial to him and to Salvin, who had died in 1898, and it was decided to use the balance of the money collected as the nucleus of an exploration fund for the benefit of the Museum; to this Fund Dame Alice and the Misses Godman later added the sum of 5000*l*. The memorial was designed by Sir Thomas Brock, and after his death the task was completed by Mr. Arnold Wright. Godman and Salvin, both of whom were fellows of the Royal Society, will be remembered for the remarkable work entitled "Biologia Centrali-Americana," which was planned by them, and finally completed by Godman after Salvin's death. It consists of sixty-three volumes; the first forms the introduction, fifty-one deal with zoology, five with botany, and six with archæology. For the work the aid of many specialists was called in, but Godman and Salvin themselves undertook the chapters on birds and diurnal lepidoptera. The whole of their marvellous neo-tropical collection was presented to the Natural History Museum; many of the specimens they had themselves collected during their travels in Central America and Mexico. In addition, Godman's gifts to the Museum were many and valuable. The tablet hangs on the wall at the head of the main stairs in the Central Hall on the east side of the statue of Darwin.

THE Report for the year 1922 of the National Physical Laboratory extends to 227 pages and is provided with an index of 24 pages. Sufficient information is given to allow the reader to understand the methods in use at the Laboratory and to follow the advances made. The diagrams and illustrations add materially to the value of the report from this point of view. The number of tests made during the year is still on the down grade, as one would expect from the statistics of trade. The various research boards and government departments continue to depend on the Laboratory for the conduct of the investigations they initiate, but the Executive Committee has found it advisable to appoint a research committee consisting of Sirs J. J. Thomson, W. H. Bragg and E. Rutherford to assist in the organisation of research at the Laboratory. This committee has made valuable suggestions as to the future work and needs of the Laboratory. There have been few changes in the senior staff during the year, and those that have taken place are due to other government departments claiming men with special knowledge. An extension of the metallurgy building which had

been needed for some time has been completed and is now in use, but the work in the physics building is still congested.

An opportunity has been afforded us to examine and test the Hatchett planimeter and the pantograph designed and manufactured by W. H. Harling, 117 Moorgate, E.C. 2. The planimeter is very simple and compact in form: after a little practice it can be made to give results of considerable accuracy. The writer has tested it on variously shaped areas of different sizes, with good results. The pantograph is a more complicated instrument, designed on the principle of simple parallelograms, and can be set to sixteen different ratios. Geometrically, the instrument seems to be quite satisfactory. In use, however, one or two faults can be detected. First, there is not enough pressure on the pencil point to produce a useful drawing. Second, the pencil is not steady, there being insufficient constraint for keeping it perpendicular to the plane of the instrument. If these faults are remedied, the pantograph should prove very useful. Both instruments are offered at moderate prices.

The Milroy Lectures on "Canned Foods in relation to Health," which were delivered a short time ago by Dr. W. G. Savage, are to be published in the autumn, in the Cambridge Public Health Series, by the Cambridge University Press.

Messrs. J. and A. Churchill are about to publish "Clouds and Smokes: the properties of disperse systems in Gases," by Dr. W. E. Gibbs, in which will be described the various ways in which disperse systems in gases can be formed; their mechanical, thermal, optical, and electrical properties, and the conditions which determine their stability are discussed. This information is then applied to the practical problems of meteorology, fume condensation, gas filtration, the manufacture of substances in a finely powdered condition, and the use of smoke in warfare.

Our Astronomical Column.

The Great Perseid Meteor Shower.—Mr. W. F. Denning writes: "The maximum of the Perseids occurred in 1921 on the morning of August 12, and the earth may be expected to be in the same position of its orbit in the early afternoon of August 12 next. There may therefore be no very rich shower, though one may possibly recur in Japan and in the East.

Our acquaintance with the distribution of the Perseids is, however, by no means perfect, and it is fairly certain that a fairly good display will be observed in England this year if the weather allows suitable observations to be made. The moon being new at the time of the maximum will be a favouring feature.

Observations should be made on the early morning of August 12 and during the night following that date. The hourly number of meteors should be counted, and the apparent paths among the stars of the larger ones should be accurately recorded so that their real paths may be computed.

It will be interesting to note if there are any strong displays of the minor radiants of this period, such as the Cepheids, Cygnids, Lyrids, or Arietids."

Observations of Jupiter.—*L'Astronomie* for July contains three drawings of Jupiter on April 24 and May 1 by M. Pierre Feurtey, using an equatorial of 0·19 metre aperture screened down to 0·14 metre. The Red Spot, the tint of which is described as *saumon gris*, seems to have revived since last year, as it is shown quite strongly marked in the drawing of May 1, with two lighter patches in its interior, and the surrounding bays, both north and south, very dark. A row of six round white markings follows the spot, slightly to the north of it.

Several narrow dark bands cross the light equatorial zone obliquely.

Parallaxes of Fifty-seven Stars.—The Memoirs of the National Academy of Sciences (Washington), vol. xix., contains the results of the determination of the parallaxes of fifty-seven stars made by Mildred Booth and Frank Schlesinger. In twenty-two of these no previous determinations of parallax have been made. The authors point out that, without the co-operation of several institutions, a long interval would have elapsed before these results could have been made available. Thus the photographic plates were secured with the Thaw photographic refractor of the Allegheny Observatory: the measures and reductions were completed at the Yale Observatory under a grant from the National Research Council (Division of Physical Sciences) to the committee on Stellar Parallaxes of the American Astronomical Society. The measuring machine was purchased several years ago with a grant from the Draper Fund of the National Academy of Sciences. The measurements and computations were carried out by Miss Booth, the methods employed having been previously published. The average number of comparison stars used was 3·8, and the average number of plates for each region was 15. It is interesting to note that a great many of the stars in the list are double; thus nearly every object is one of more than average difficulty, the stars having in fact been selected on that account from a long list awaiting attention at Allegheny. A summary of the parallaxes is given in a table showing the visual magnitude and spectrum type, total proper motion, relative parallax and probable error, and finally, the probable error for one good plate.

Spectroscopic Binaries.—The Dominion Astrophysical Observatory, Victoria, is determining orbits for a number of these binaries. The chief interest in this research is the material for determining the average mass of stars of each spectral type. The masses of individual stars are indeterminable owing to the uncertainty of the inclination, but in studying a large number of binaries we may assume that the inclinations follow the law of random distribution. The elements of the following three stars have lately been determined:

	Spectral Type.	Period.	Mass in terms of sun's mass.
BD 44° 3639	Oe 5	48·608 days	0·374
Boss 4870	B 2	1·0309 ,,	0·00019
ϕ Aquilae	A 2	3·3204 ,,	0·0192

The first is of special importance, since few masses of this type are known. One spectrum only is visible in each of these cases, so the companion is likely to have smaller mass. In the Oe 5 spectrum, the sharp H and K lines do not share in the oscillations and give a velocity of −11·3 km./sec., as compared with −5·8 km./sec. for the centre of gravity of the system.

Research Items.

TONGAN ASTRONOMY AND THE CALENDAR.—In one of the Occasional Papers of the Bernice Pallahi Bishop Museum (vol. viii. No. 4, 1922) Mr. E. E. V. Collocott has collected all that can be known of Tongan astronomy. They had the vaguest notions of the heavens and of the relations of the sky to stars, sun, and moon. They treated astronomy as a branch of navigation, but since the use of the mariner's compass, few if any living Tongans are able to point to or name more than a very small proportion of the stars. Practically all the available star lore of the Tongans is included in sailing directions written by the late Tukuaho, who was Premier of Tonga about thirty years ago, and this account, copied by permission of his son Tungi, consort of H.M. the Queen of Tonga, has been followed by Mr. Collocott in compiling this paper.

DISCOVERY OF AN EARLY PALÆOLITH IN NORFOLK.—In the *Antiquaries Journal* for April (vol. iii., No. 2), Mr. J. Reid Moir describes the discovery by Mr. J. E. Sainty of an Early Palæolith from the Glacial Till at Sidestrand, Norfolk. The specimen contains, in its interstices, material which, in appearance, is identical with the matrix of the Boulder Clay, and the colour of the flake-scars is precisely similar to the broken surfaces of many flints in the Till at Sidestrand. Mr. Reid Moir believes that the implement originally belonged to the Upper Freshwater Bed, the highest division of the Cromer Forest Bed Series. The Early Palæolithic implements of these strata are believed to afford the only evidence in East Anglia of the warm climate prevailing in Early Palæolithic times, and possibly representing the Günz-Mindel interglacial epoch. This gives definite evidence that the manufacture of early Chellean hand-axes was begun in what is now East Anglia, before the arrival of the glaciers which were responsible for the deposition of the Lower Glacial beds. Mr. Sainty has generously presented this Sidestrand implement to the Ipswich Museum.

CHROMOSOME MOVEMENTS IN NUCLEAR DIVISION.—Many attempts have been made to explain the forces at work in connexion with the mitotic figure in nuclear division. Attractions and repulsions are evidently involved, and these may result partly from the presence of electrical charges on the colloidal particles. The latest contribution to this subject is by Mr. Graham Cannon (*Journ. of Genetics*, vol. 13, No. 1), who applies Lamb's hypothesis that the centrosomes are pulsating or oscillating bodies, and also extends it to a consideration of the movements of the pronuclei in fertilisation. Mr. Cannon discusses many of the consequences which would follow from this assumption, but as yet there is little direct evidence that the centrosomes are actually centres of oscillation or pulsation. A very interesting feature included in the paper is the demonstration, by means of figures of the chromosome groups in the equatorial plate of various animals, that the chromosomes do in fact arrange themselves like floating magnets, the particular arrangement depending upon the number of bodies present. This result was predicted by R. S. Lillie in 1905.

EFFICIENCY IN COTTON WEAVING.—As the number of studies made in different industries and in different departments of the same industry increases it becomes more and more apparent that there are conditions militating against efficiency which are of an alterable character. A careful study of efficiency in cotton weaving, by Mr. S. Wyatt (Reports of the Industrial Fatigue Research Board, No. 23; London: H.M. Stationery Office, price 3*s.* net), demonstrates once more the value of natural, as against artificial, illumination; this factor has been shown in previous reports to hold true in silk weaving and in fine linen weaving. The relations between humidity, high temperatures, and efficiency are very well brought out; under existing conditions it is maintained that the best conditions for productive efficiency in weaving, in humid sheds of the type investigated, seem to be with a dry bulb temperature of 70°-75° F. and a relative humidity of 80-85 per cent. The writer also shows that, on the two-break day system, the efficiency during the pre-breakfast spell is consistently low. Various other aspects of the problem are considered, such as personal ability, individual differences, incentives and fatigue, and suggestions are given both for the amelioration of the conditions of the cotton weaver and for further study. The Fatigue Research Board in its cautious preface to the report is careful to point out the limits within which the conclusions must be interpreted. It is interesting, though, to note that in considering one report after the other there is a rapidly increasing weight of evidence in quite definite directions.

THE CONTROL OF THE PADDY STEM BORER IN INDIA.—In Memoirs of the Dept. of Agriculture in India, Entomological Series, vol. vii. No. 13, 1923, Mr. E. Ballard gives an account of experiments on the control of the paddy stem borer *Schœnobius incertellus* in the Godaveri delta. The insect occurs wherever paddy is grown in the East, and causes an annual loss of 10 per cent. of the entire Indian crop. Various schemes have been put forward for controlling the insect, the use of light traps being largely advocated. Mr. Ballard expresses doubts as to the efficacy of the latter method. Such traps are expensive and liable to be stolen, sometimes they only attract moths towards the light without destroying them, while many of the moths have laid their eggs before being trapped. The method of selecting attacked seedlings at the time of transplanting gives some hope of constituting an effective means of control. Close cutting, used in combination with seedling selection, should also destroy a large proportion of the larvæ from which the succeeding crop could be infected. The extent to which stubble helps the insect to tide over the time between the crops needs research. The natural insect parasites of the borer also require study, and the possibility of growing immune varieties of paddy should be tested.

CORRELATION OF OIL-SANDS: THE DAKOTA GROUP.—The correlation of oil-bearing sands on the basis of palæontological or petrographical work or both, is a phase of the geology of petroleum which has not always received the detailed attention in the United States that it undoubtedly merits. It is therefore gratifying to note that the importance of such work is now more generally realised, and Mr. W. T. Lee's contribution to Bulletin 751 on the "Continuity of some Oil-bearing Sands of Colorado and Wyoming" is a case in point. As Mr. Lee remarks, nearly every important sandstone in the great Cretaceous system of the western states contains oil, and the differentiation and correlation of these oil-horizons form problems the ultimate solution of which is demanded before this vast region can be economically developed. The rocks dealt with in this report belong principally to the Dakota Group, and apart from valuable local details regarding the different sands and shales

included, the author establishes the important stratigraphical fact that there is no single, definite, persistent and easily recognisable sandstone corresponding to the formerly so-called Dakota Sandstone, but that a group of sediments to which the name Dakota is given represents successive accumulations of sediments near the strand-line of an advancing Cretaceous sea, presumably Upper Cretaceous, but not necessarily so. Hence the group differs in age from place to place according to the time taken by the advance of this strand-line across intervening distances.

WEATHER AT FALMOUTH IN 1922.—Falmouth Observatory has recently issued meteorological notes and tables for the year 1922, prepared by Mr. J. B. Phillips, superintendent of the Observatory. The mean barometric pressure for the year was 29·96 in., which is 0·02 in. below the normal. The mercury reached a maximum height of 30·79 in. during November, which is also the highest November reading on record since the commencement of observations in 1871. The high-pressure system associated with this reading prevailed from November 10 until December 15. In July the barometer fell to 28·98 in., which is the only record with the barometer below 29 in. in July. Temperature reached its highest reading, 75° F., on May 31, and the minimum, 28° F., on March 23. The summer was cool, the day temperature registering 70° F. or above on 6 days only, 4 in May and one in June and September respectively. Bright sunshine for the year registered 1663 hours, which is 90 hours less than the normal; the brightest month was May with 260 hours of sunshine, and the least sunny was December with 48 hours. Rain fell on 211 days, yielding a total of 45·75 in., which is 0·14 in. more than the normal. December, which is normally the wettest month of the year, had the highest monthly rainfall, amounting to 8·02 in., of which 7·64 in. fell in the last 16 days. During the year the equability of the climate of Falmouth withstood two severe tests. In an exceptionally cold period at the beginning of April, of 108 stations in the British Isles it was one of 9 at which the temperature did not fall below 34° F., and during a hot spell from May 21 to 24, when temperatures above 80° F. were general on the coast, the maximum did not rise above 68° F.

COMMERCIAL PRODUCTION OF OXYGEN.—The *Chemical Trade Journal* for June 15 contains an account of a long paper by Mr. T. Campbell Finlayson on "Industrial Oxygen," which was read before the Institution of Chemical Engineers. The aim of the work was to find a means of producing oxygen industrially at a price of 1*s.* per 1000 cu. ft. This was not realised, but a large number of possible methods were tried, some of which were found to be quite practicable. Chemical methods are impossible, as they are invariably too expensive; the most promising method is based on the differential solubility of oxygen and nitrogen under pressure in different liquids. Mr. Finlayson remarked that the discovery of a more suitable solvent might put the matter in a very different light. It will be recalled that this method was used, with water as a solvent, by Mallet half a century ago.

RECORDING WATER-LEVELS ELECTRICALLY.—A new form of electric transmission, for long-distance indication of variations in water-level and similar purposes, has been devised and put on the market under the designation of the Telechron Transmitter. The drawback in regard to systems of electric transmission in such cases is that dependence has to be placed on the unfailing action of the receiver to record the series of impulses sent out from the transmitter. With the ordinary electro-magnetic apparatus, owing to difficulty in exciting the magnetic field with sufficient promptitude, there is a possibility of failure to transmit signals which succeed one another rapidly. In other words, the receiver and transmitter are liable to "get out of step." In the Telechron instrument, signals are transmitted at a constant rate, independent of the speed of movement of the float or other actuating agent; the impulses are accumulated by the transmitter and are despatched in sequence at a rate within the capacity of the receiver to record them. It is thus possible for a float to make a rapid rise without the omission in the recorder of any one of the impulses in the series generated. Falls in level are equally accounted for, and when alternations take place rapidly the instrument records the net difference in either sense. It is possible to store up any number of impulses in the transmitter, though for practical purposes it is only necessary to provide for a hundred revolutions of the counter. Should the circuit by any chance be broken or the battery fail, the transmitter automatically sets itself and the receiver in step on the restoration of the current. There are other possible applications of the Telechron besides the long-distance record of water-levels; it is a trustworthy telegraph to indicate the position of a ship's helm, or of a lock-gate, or other moving object. It can also be adapted to the purpose of recording the pressure in gas mains. The apparatus is introduced by the Telechron Electric Transmitter Company, of 53 Victoria Street, S.W.

LUMINESCENCE.—Luminescence, as defined by Wiedemann, includes all cases of radiation except those due to temperature alone. In this sense the term is used in the valuable report published as a Bulletin of the National Research Council of the United States, entitled, "Selected Topics in the Field of Luminescence." The report, which is the work of Prof. E. Merritt, E. L. Nichols, and C. D. Child, covers a wide range, but most of the topics chosen for discussion are connected with fluorescence and phosphorescence. Prof. Merritt, who is responsible for the greater part of the volume, contributes an important chapter on theories of luminescence, dealing with the work of Lenard, Kowalski, Kennard, Baly and Perrin. A perusal of this chapter confirms the opinion that the most important problem at the present time in the field of luminescence is that of developing some satisfactory and comprehensive theory which may serve as an aid in correlating the observed phenomena and as a guide in planning new investigations. Such a theory must link together the varied subjects dealt with in later chapters—luminescence at high temperatures, luminescence and photo-activity, and, in particular, fluorescence and chemical change. Special attention may be directed to the work of Pringsheim, who, after a somewhat extended discussion of photochemical theories of fluorescence, is inclined to decide against such theories, putting forward certain suggestions in explanation of the chemical changes that so often occur in connexion with fluorescence. In the bibliography of luminescence, forming the last chapter of the report, Dr. J. A. Becker has made a serious attempt to include references to all books and articles on luminescence that have appeared between the years 1906 and 1922. References to papers on spectroscopic work have been included when, as in the case of flame spectra, they appear to have a direct bearing on the theory of luminescent radiation.

The Electron in Relation to Chemistry.

THE Faraday Society's conference on "The Electronic Theory of Valency," held at Cambridge on July 13 and 14, may be regarded as marking a new stage in the welding together of physics and chemistry, which has been so notable a feature of the recent history of these two sciences. The conference was attended by about 120 delegates from different universities, about half of whom were drawn from outside Cambridge. Some forty visitors were entertained in Trinity Hall, through the kindness of the master and fellows, to whom a deep debt of gratitude is due for contributing in this way to the pleasant social features of the conference. The foreign guests included Prof. G. N. Lewis, Prof. W. A. Noyes, Prof. Lyman, and Prof. Victor Henri of Zurich; the physicists included Sir J. J. Thomson, Sir Ernest Rutherford, Sir William Bragg, Prof. Barton, Prof. W. L. Bragg, Prof. Porter, Prof. Rankine, Dr. F. W. Aston, and Mr. R. H. Fowler; the chemists, in addition to Sir Robert Robertson, the president of the Faraday Society, included Sir William Pope, Prof. Heilbron, Prof. Lapworth, Prof. Lowry, Prof. Robinson, Prof. Smithells, Prof. Thorpe, Mr. C. R. Bury, Dr. Flürscheim, Dr. W. E. Garner, Dr. Henstock, Dr. Kenner, Mr. W. H. Mills, Mr. E. K. Rideal, and Dr. N. V. Sidgwick.

The conference was held in the new Department of Physical Chemistry, which is housed very appropriately in a block of buildings lying between the Chemical Laboratory in Downing Street and the Cavendish Laboratory in Free School Lane. These buildings, which were formerly in the occupation of the Department of Engineering, now provide ideal quarters for work in physical chemistry. They have been completely refitted and are admirably suited to their new use; they are also so commodious that there is a reserve of floor-space which has been loaned to workers from other departments, pending the time when it may be required for further extensions of physico-chemical work. Tea was served before the conference opened, in the large laboratory of the Hopkinson wing, which was erected in 1900 as a memorial to the late Prof. Bertram Hopkinson and his son, while the discussions were held in the lecture theatre adjoining.

The Friday afternoon session, dealing mainly with the application of the electronic theory to the problems of inorganic chemistry, was presided over by Sir J. J. Thomson, who in his opening address referred to the fact that, while the force which retains the electrons in an atom is proportional to the positive charge on the nucleus, the disruptive force which tends to make them scatter is proportional to the third power of their number, so that a limit is set to the number of electrons which can be crowded into one atom. The law of force is such that when the number of electrons is small, the octet is a particularly stable grouping; but with a different law of force, a sextet might be more stable than an octet. The problem of molecular structure can be attacked most readily by the study of cases of substitution; thus the electric moment introduced on replacing hydrogen by chlorine can be calculated, and measurements of the specific inductive capacity of molecules of different types have shown that this moment is constant in magnitude.

Prof. G. N. Lewis, in presenting his paper on "Valence and the Electrons," directed attention to the reconciliation which has recently taken place between the views of physicists and chemists in reference to the structure of the atom. Since physicists have now adopted a model in three dimensions, it is possible to regard the orbit of the electron as having a fixed orientation, although the electron itself is in rapid motion. The chemist's theory of static electrons has, therefore, been merged quite naturally into a scheme of static orbits. Prof. Lewis directed attention to the fact that, in Bohr's atomic structures, each of the rare gases from neon to niton, and all the stable elementary ions, possess eight electrons in the outer shell, thus affording full justification for what came to be known as "the octet theory." The fundamental phenomenon of chemistry is, however, the formation of *pairs* of electrons; and of some hundred thousand known substances only about half-a-dozen contain uneven numbers of electrons. This pairing may perhaps be due to magnetic forces, since unpaired electrons always give rise to a magnetic moment. When four of these electron-pairs are grouped at the corners of a regular tetrahedron the still more stable configuration of the octet is obtained.

Prof. Lewis attaches great importance to the view that the sharing of a pair of electrons constitutes a chemical bond between two atoms. When this bond is broken, the electron-pair usually remains attached to one atom, which acquires a negative charge, while the associated atom (which loses its share of the electron-pair) acquires a positive charge on disruption. This contrast is described in Langmuir's nomenclature as the conversion of a "covalence" into an "electrovalence"; and most English readers have accepted this nomenclature as an essential feature of the "Lewis-Langmuir hypothesis." Prof. Lewis, however, regards the ionised bond as being no longer a bond at all, and even objects to the use of the term "valence" to express the electrical state of the atom, although for nearly seventy years bismuth and aluminium have been described, like phosphorus and nitrogen, as tervalent elements.

The two following papers, by Mr. R. H. Fowler on "Bohr's Atom in Reference to the Problem of Covalency" and by Dr. N. V. Sidgwick on "The Nature of the Non-polar Link," were of interest as exhibiting two parallel lines of thought in the application of Bohr's theory of the structure of atoms to the unsolved problem of the electronic structure of molecules. The close agreement between the conclusions reached on this subject at Oxford and at Cambridge is noteworthy. As might perhaps have been anticipated, the Cambridge physicist was much more apologetic than the Oxford chemist, since he evidently realised more fully the risks that must be taken when forsaking the mathematical concepts, verified by observations of spectra, on which the structure of the atom is based, for purely qualitative conceptions of molecular structure, which are at present beyond the range of mathematical analyses and of experimental verification. The chemist, on the other hand, boldly translating the shared electrons of Lewis into shared orbits (compare Dr. N. P. Campbell's letter in NATURE of April 28, p. 569), was ready at once to gather a harvest of new conceptions from this speculative extension of Bohr's theory. A study of the printed papers shows, however, no important discrepancies between the views of the two authors as to the results of extending the theory of orbits from atomic to molecular structure.

In the discussion following upon the reading of these papers, Sir J. J. Thomson pointed out that two electrons are not necessary to make a bond, since H_2^+ is one of the most persistent aggregates met

with in positive rays, although there is only one electron left to hold the two protons in combination. To this Mr. Fowler replied that although this may be stable for an indefinite period in a vacuum, aggregates of this type appear to be quite incapable of resisting chemical combination—perhaps because an odd electron passing from one nucleus to the other would impart an electrical charge alternately to one atom and the other, giving rise to an unstable condition which would be particularly ready to undergo chemical change.

Prof. W. A. Noyes, after reviewing briefly the history of the development of the theory of ionisation, laid stress on the fact that the distinction between polar and non-polar union is one of degree and not of kind, the fundamental factor in both types of union being the pairing of electrons. He also directed attention to the fact that the elements, such as lithium, sodium, potassium, rubidium, and cæsium, which are monoatomic in the gaseous condition, are exactly those which have a single valency-electron in the outer shell.

Sir William Bragg made an important statement in reference to the lengths of the carbon chains in the fatty acids and esters. Each additional carbon atom in the alcohol radical increases the length of the carbon chain by 1·22 Å.U.; but for the acid radical the average increment is only 0·97 Å.U. This remarkable result can be explained, while maintaining a fixed distance of 1·5 Å.U. between the carbon atoms, by assuming, on the alcohol side of the molecule, a simple zigzagging of the chain of atoms, with a fixed tetrahedral angle of 109° 28′, the branching of the chain being to the left and right alternately. The increment on the acid side of the chain can be explained by assuming the formation of a zigzag chain of another type, the deflexions being in the order LLRRLL, etc., instead of LRLRLR. These two forms of zigzag appear to be initiated by the two types of oxygen-linking in the –CO.O– group, and then to be rigidly maintained in the two chains. The structure suggested on the acid side of the molecule may explain the alternation of physical properties observed in the well-known odd and even series of acids, since the increment of length is alternately parallel to the chain and inclined at an angle of 109° 28′ to it.

At the close of the session Prof. Victor Henri made a brief communication in anticipation of the important paper which he delivered on the following day. The discussion took place under tropical conditions, which were so extreme that the session was adjourned before the discussion had become completely informal. An informal discussion was, however, carried on in the cooler atmosphere of the evening in the fellows' garden of Trinity Hall, to which some sixty delegates adjourned after dining together in the Hall of the College. The bringing into direct personal contact of workers who had previously known one another only by correspondence, or by reading one another's published communications, was a most valuable feature of the conference, and full advantage was taken of the opportunities thus presented.

The discussion, on Saturday morning, of the applications of the electronic theory of valency to organic chemistry, was presided over by Sir Robert Robertson. In opening the discussion, Prof. Lowry urged that the electron has come to stay, and that sooner or later organic chemists must take into consideration the electronic structure of atoms and molecules. These may prove to be a mere translation into a new language of the structural formulæ of Kekulé and van 't Hoff; giving rise to a new nomenclature but to no new conceptions. This is, however, unlikely in view of the enormous advances that have followed from the discovery of Dalton's atom, and of each fresh detail of its structure. The electronic theory of valence has already made a contribution of real value by discriminating between two types of valency, since a single bond can now be classified as depending either upon electron-sharing or upon electron-transference. Prof. Lowry's own contribution had consisted in the suggestion that a double bond may assume a form in which one linkage of each type is present. This has led to a number of novel conclusions which have been set out in a paper published in the April number of the Journal of the Chemical Society and in a paper on "Intramolecular Ionisation in Organic Compounds" contributed to the present discussion.

In summarising a second paper on "The Transmission of Chemical Affinity by Single Bonds," Prof. Lowry raised the question as to how many types of valency the chemist would wish the physicist to provide, and how many different mechanisms must be invented to account for the transmission of chemical affinities through chains of atoms. Prof. Lowry believes that only two types of valency are necessary, and that principal and subsidiary valencies, partial valencies, conjugated double bonds, carbonium bonds, mobile hydrogen atoms, centric bonds and paralinkages in aromatic compounds, are all manifestations of those electrostatic forces which Langmuir describes as electrovalence. In the same way, the unidirectional "general" effect, and the "alternating" effects observed in conjugated chains, appear to account for nearly all the phenomena observed in the transmission of chemical affinity. Lapworth and Flürscheim have suggested cases in which alternating effects appear to be produced in chains of single atoms; but other explanations (such as the steric effects described by Sir William Bragg) appear to be capable of accounting for most of these observations, and further evidence is needed before a third mechanism of transmission need be admitted. The evidence now brought forward by Lapworth and Robinson may perhaps provide the unexplained residue of observation which would make such a mechanism necessary. Prof. Lowry's paper also contained a vindication of Vorländer's view that, when its direct neutralising action is eliminated, the amino-group possesses well-defined acylous properties; it is therefore no anomaly for an amino-acid to be stronger than the fatty acid from which it is derived.

Prof. Lapworth, in communicating a paper on "Some Recent Contributions to the Theory of Induced Alternate Polarities in a Chain of Atoms," described six different theories which have been put forward in order to account for these phenomena. In criticism of the previous speaker, he stated that he himself twenty years previously emphasised the tendency of organic compounds to assume a "homogeneous" in place of a "heterogeneous" distribution of valency. This is precisely the same phenomenon that Prof. Lowry discussed under the heading of "Crossed Polarities." As evidence of alternate polarities in chains of atoms held together by single bonds he quoted the biochemical oxidation of butyric acid to β-hydroxybutyric acid and then to aceto-acetic acid. This case has also been quoted independently by Robinson.

Prof. Robinson contributed a paper on "Octet Stability in Relation to Orientation and Reactivity in Carbon Compounds." He directed attention, as Prof. Lapworth had done, to the fact that optical activity is often preserved in chemical changes,

although, if the intermediate stages are those which are conventionally postulated, the optical activity must necessarily disappear, since the intermediate product would be symmetrical. The preservation of asymmetry can, however, be explained by means of partial valencies, through which the asymmetry of one atom is maintained until it has been stabilised again either in the same atom or in a different one.

The bearing of the theory of polarity on the reactivity of organic compounds was discussed by Mr. E. K. Rideal, and, as illustrating this aspect of the problem, Mr. R. G. W. Norrish described some experiments which he has just carried out, according to which the union of ethylene and bromine is almost stopped by enclosing the mixed gases in a vessel lined with paraffin wax, whereas in contact with the polar surface of a glass vessel combination takes place rapidly.

In the general discussion, to which about a dozen different speakers contributed, Prof. J. F. Thorpe urged that the theory of polarity "explains everything but predicts nothing," in marked contrast to van 't Hoff's stereochemistry, which made organic chemistry into the most exact of all the sciences. This contention was strenuously denied by Mr. Burkhardt from the Manchester laboratory and by Profs. Noyes, Lapworth, Heilbron, and Robinson, who proceeded to put on record two definite predictions in order to get over the difficulty that under normal conditions the prediction and the verification are published together, so that the reader cannot be quite certain which really came first. Dr. Flürscheim also replied in a very vigorous manner to the criticisms by Prof. Lowry of his views in reference to the influence of substitution on the strength of carboxylic acids, and urged that in several examples the formation of internal salts, which had been suggested as an alternative explanation by Prof. Lowry, cannot in fact take place. Prof. Lewis directed attention to the fact that the breaking of a double bond does not necessarily get rid of *cis* and *trans* isomerism, even if free rotation can take place; and in support of this view Mr. Bury quoted the fact that quadrivalent sulphur compounds retain their optical activity even when one of the four groups is ionised.

In the final session of the conference, Prof. Victor Henri presented a paper on "Molecular Polarity deduced from the Study of Absorption Spectra." This proved to be a most remarkable contribution, in which the application of considerations based on the quantum theory led to the conclusion that quantified motion may occur in electrons, atoms, or molecules, giving rise to broad absorption-bands, narrow absorption-bands, and a fine structure of these bands, respectively. By making use of a source of continuous ultra-violet light, Prof. Henri has been able to study the fine structure of the absorption bands of a large number of compounds, and in some instances to measure as many as two thousand bands in the fine structure. A large number of photographs were shown to illustrate the various types of absorption spectra. Prof. Henri's paper produced a very profound impression by the masterly character both of the theory and of the experiments which he described. It may well mark a new era in the history of absorption spectra. In apologising to Prof. Henri for the fact that the late hour did not allow of an opportunity for discussion, the president added that the question of holding a general discussion on absorption spectra is already under consideration by the council of the Faraday Society, and that such a discussion would allow of a fuller consideration of the view which Prof. Henri had put forward.

International Conference of Phytopathology and Economic Entomology.

THE first International Conference of Phytopathology and Economic Entomology was held in Holland on June 24-July 2 by the kind invitation of the Netherlands Government in co-operation with the authorities of the various laboratories and institutes conducting work on agricultural phytopathology and entomology. The Conference was noteworthy as being the first occasion on which phytopathologists and entomologists from all countries have been invited to meet together to discuss matters of mutual interest. Prof. H. M. Quanjer of Wageningen, presided over the Conference, while Dr. L. O. Howard, Chief of the United States Bureau of Entomology, acted as president of honour. Upwards of 65 members attended—in addition to the Dutch participants—representing some 26 countries. A report of the Conference, giving an account of the demonstrations, papers read, etc., will be issued by the Committee of Management (obtainable from the Secretary, Mr. T. A. C. Schoevers, of the Netherlands Phytopathological Service, Wageningen), but in the meantime the following brief account may be of interest.

Members assembled at Wageningen on June 24, when an address of welcome was delivered by Prof. Kielstra, Rector Magnificus of the University. On the following morning the Conference was formally opened by H.E. the Minister for Home Affairs and Agriculture, and during the day members attended the inauguration, by Jonkheer van Citters, of the new Laboratory for Potato Research in which Prof. Quanjer's Department is now housed. In the laboratory and adjoining experiment station experiments of great interest, notably in connexion with the "virus" diseases of the potato, were inspected. After spending two days in conference, the members divided into two parties, one visiting Groningen and the other Boskoop, Aalsmeer and Haarlem. The first party inspected the practical application of Prof. Quanjer's experiments in the selection fields and farm of Dr. O. Botjes, who demonstrated his methods of obtaining "seed" potatoes on a large scale entirely free from virus diseases, and the second visited nurseries producing ornamental plants, shrubs and bulbs; at Lisse (near Haarlem) they visited Dr. van Slogteren's new laboratory for the study of bulb diseases, and were treated to an excellent address and to demonstrations. The two parties combined forces again at the laboratory of Prof. Westerdijk, Director of the W. C. Scholten Phytopathological Laboratory at Baarn, where the final papers were read and the discussions concluded. Subsequently H.E. the Minister for Home Affairs and Agriculture held a farewell reception at the Hague, and members were entertained to dinner at Scheveningen. Many members remained until the following week to take part in an expedition to the glass house district of the Westland.

Within a short space it is impossible to do justice to the papers read. Two subjects were, however, specially prominent—namely, (1) the research, both botanical and entomological, which centres round the

plant-diseases of the "virus" type, and (2) the efficiency or otherwise, of controlling the spread of insect and fungus pests from one country to another by means of a phytopathological service.

Discussions on the latter concerned chiefly plant import regulations and quarantines, the point of view of the exporting country being ably expounded by Mr. van Poeteren, who is director of the Netherlands Phytopathological Service. The controversial and difficult nature of this subject is well known, and it is satisfactory to record that the following resolution was approved:

"The representatives of all nations assembled at the International Phytopathological Conference at Wageningen, June 25-30, 1923, desire to place themselves on record as in full agreement with the essentials of international trade and commerce in living plants and plant-products, namely, reasonable freedom from all insect-pests and plant-diseases of all kind of materials imported into or exported from any country."

It should also be mentioned that so greatly impressed were members with the results of the Conference in bringing about international sympathy and co-operation as to the control of diseases and pests, that it was considered imperative that similar conferences under the same title should be held in future, and a small committee, under the chairmanship of Prof. Quanjer, with Mr. Schoevers as secretary, was appointed to undertake provisionally the duties of arranging for the next conference and of dealing with the various resolutions which had been passed.

This brief summary would be incomplete if some reference were not made to the hospitality and kindness experienced. Special mention must also be made of the admirable manner in which Prof. Quanjer carried out his duties as president, and the debt members owe him for rendering the discussions clear to all by rapid translation. As secretary, Mr. Schoevers was untiring, working literally night and day for the good of the Conference.

Sir William Thiselton-Dyer.

TRIBUTE FROM BRITISH BOTANISTS.

On July 28 Sir William Thiselton-Dyer attained his eightieth birthday and was the recipient of the subjoined letter from botanists throughout the country. Sir William's work as assistant director of the Royal Botanic Gardens, Kew, under Sir Joseph Hooker, and then as director for a memorable period of twenty years, is so well known that it is not necessary to refer to the many important things he did during his term of office. The present condition of the Gardens, and the prestige of Kew all over the world, are sufficient testimony to his ability and prescience. We beg to extend to Sir William in his retirement our congratulations and best wishes that he may long continue to enjoy his health and carry on his botanical activities.

Dear Sir William,

The occasion of your eightieth birthday affords us the opportunity of which we gladly avail ourselves, not only of offering you our congratulations upon having attained so venerable an age, but also of assuring you of our continued regard and esteem. In doing so we who sign this letter do but acknowledge our indebtedness to you for the inspiration and guidance which we, both as teachers and researchers, have derived directly or indirectly from your own early work as a professor of botany. We regard that work, and more especially the courses of practical instruction conducted by you at South Kensington in the years 1875 and 1876, as having inaugurated the renaissance of the study of the structure and functions of plants which had been so brilliantly carried on by British botanists in earlier times. It must, we feel sure, afford you great and justifiable satisfaction to contemplate the marvellous development of such studies in this country during the years that have passed since you quickened them into new life.

The professorial career on which you had embarked so brilliantly was unfortunately, as it may have seemed at the time, brought to a close by your appointment to the assistant directorship of Kew in 1875 and your subsequent appointment as director ten years later. The work that you were enabled to carry out at Kew has been of such national importance, that, however much we may regret the loss of the stimulating influence you would undoubtedly have exerted as a professor, we all realise the great and lasting services you have rendered to botany, not only from the purely scientific point of view, but also in relation to the development and encouragement of botanical enterprise throughout the British Empire.

Another notable result of the interest you inspired was the successful launching of the *Annals of Botany*, which has come to be one of the leading botanical periodicals of the world. We do not forget that it was your enthusiasm that turned the scale when the question of "to be or not to be" hung in the balance. The *Annals* is a lasting monument to your courage and prescience.

It would need a lengthy document were we to attempt to set out in detail the value of your many efforts for the promotion of our science, but in conclusion we feel we must refer to the noble work you did in saving the old Chelsea Physic Garden from destruction. Thanks to you, London has now a botanic garden where students and teachers can study the structure and functions of plants and pursue those studies which you did so much to promote.

With our very kind regards and good wishes,

Believe us to be, dear Sir William,

Yours very truly,

D. H. Scott	F. Keeble
S. H. Vines	A. B. Rendle
F. O. Bower	A. Shipley
Balfour	H. Wager
H. T. Brown	F. F. Blackman
D. Prain	V. H. Blackman
F. Darwin	F. W. Oliver
H. H. Dixon	A. G. Tansley
A. C. Seward	F. E. Weiss
J. B. Farmer	A. W. Hill

and all the leading botanists in Great Britain and Ireland.

University and Educational Intelligence.

Edinburgh.—At a special graduation ceremonial, held in the University Library Hall on July 25, the following members of the eleventh International Physiological Congress, then meeting in Edinburgh, were presented to the vice-Chancellor (Sir Alfred Ewing), by Sir E. Sharpey Schafer, for the Honorary LL.D.:—Prof. F. Bottazzi, professor of physiology, University of Naples; Prof. W. Einthoven, professor of physiology, University of Leyden; Prof. W. H. Howell, professor of hygiene, Johns Hopkins University, Baltimore; Prof. J. E. Johansson, professor of physiology, University of Stockholm; Prof. A. Kossel, professor of physiology, University of Heidelberg; Prof. H. H. Meyer, professor of pharmacology, University of Vienna; Prof. I. P. Pawlow, professor of physiology, University of Petrograd; and Prof. C. Richet, professor of physiology in the Faculty of Medicine, Paris.

London.—Dr. Lydia Henry has been appointed Warden of the Household and Social Science Department, King's College for Women, Campden Hill Road, W.8.

Manchester.—The Empire Cotton Growing Corporation has recently offered to the University, for a period of five years, a grant to promote study and research in mycology and entomology, more particularly the diseases of plants caused by animal and fungal parasites known to be, or likely to be, of importance to cultivators of cotton. It is made a condition of the grant that the University should admit cotton research scholars and assistants on study leave to its laboratories, and it is also asked to deal so far as it can with inquiries from scientific advisers to cotton growers. The work will be carried out in the Departments of Botany and Zoology under Mr. S. Williams and Mr. R. A. Wardle respectively. In this connexion the large and valuable collections of insects in the Manchester Museum will be of considerable assistance in the identification of insect pests, while the experimental grounds and greenhouses which the University has recently established in Fallowfield will greatly facilitate the study of plant diseases.

Sheffield.—The title of emeritus professor of mechanical engineering has been conferred on Dr. W. Ripper in recognition of the services he has rendered to the Department of Engineering and to the University.

Mr. Denton Guest has been appointed assistant bacteriologist.

Dr. K. Fassler of Freiburg (Switzerland) has been appointed, according to the *Chemiker Zeitung*, assistant and reader in mineralogy and geology at Laval University, Quebec.

The Educational Directory, 1922–23, published by the Bureau of Education, Washington, as Bulletin 1922, No. 50, contains not only the names of administrative officials—federal, state, county, town, university, college, and library—but also lists of boards, societies, and other organisations having educational aims, and a list of educational periodicals in the United States. The list of summer schools in connexion with universities, colleges, and normal schools is an astonishingly long one, containing more than 500 entries: in most cases the summer session lasts for from six to ten weeks.

The Clothworkers' Company of the City of London has offered an annual contribution of 3000*l*. for the period of five years 1923–1927 to the Imperial College of Science and Technology, South Kensington, to be applied towards the maintenance and development of the City and Guilds (Engineering) College, one of the three constituent colleges of the Imperial College of Science. This donation is supplemental to the sum voted some years ago by the Goldsmiths' Company, a gift amounting to 85,000*l*., which enabled the Engineering College to extend its premises, and is quite distinct from the annual vote of 5000*l*. from the City and Guilds of London Institute which has been paid to the Imperial College since the charter was granted some fifteen years ago and applied to the City and Guilds (Engineering) College. It is another indication of the value which practical men in the City of London attach to the research and general teaching in science specially in relation to industry.

In 1917 the Government, acting through the Board of Education and the Department of Scientific and Industrial Research in conjunction with the London County Council and the Governors of the Imperial College, South Kensington, established at the Imperial College, for a period of five years in the first instance, a Department of Optical Engineering and Applied Optics, in the charge of Prof. F. J. Cheshire. As the Department was originally sanctioned for five years only, the question of its future has recently come up for consideration, and it has been decided that it shall be put upon the same basis as regards permanency as the other Departments of the College. The work of this Department should do much to prevent a recurrence of the position in Great Britain in 1914, when optical manufacturers were severely hampered by the insufficient number of optical experts available both for the scientific direction of production and also for the designing and computing of new optical systems demanded by the Government.

In view of the jubilee celebration of the Cambridge University local lectures on July 6-9, special interest attaches to a review published in the May number of *School Life* (Washington, U.S.A.) of university extension work in America. The writer, who is president of the National University Extension Association formed in 1915, recalls that this work has been carried on in America since the inauguration of the Chautauqua gatherings in 1885, but it was not until 1906 that the University of Wisconsin, the pioneer State university in this field, organised its university extension division as an extramural college with a dean and separate faculty. Since 1913 the movement has spread so rapidly that now practically every institution of learning—university, college, normal, technical, or professional school, whether public or private, engages in some form of extension activity. The goal of the movement is thus described: "to fit every man and woman for his or her job, thereby making a better economic and social asset for the State." This insistence on the ideal of service to the State is characteristic of American writers on this subject and on elementary and secondary education. The National Association aims at standardising the character and content of courses, conditions of admission, etc. Among important recent developments of extension work in America are: co-operation with agencies such as state medical and dental societies and boards of health, extension courses for medical practitioners, and the utilisation of broadcasting stations. Nearly every state has now a correspondence school system supported by taxation, usually organised as a department of the state university.

Societies and Academies.

CAMBRIDGE.

Philosophical Society, July 16.—Mr. C. T. Heycock, president, in the chair.—W. M. H. **Greaves**: The possible mechanics of the hydrogen atom.—S. **Chapman**: The motion of a neutral ionised stream in the earth's magnetic field.—J. D. **Bernal**: Analytical theory of crystals.—H. F. **Baker**: Two geometrical notes: (1) Theory of confocal quadrics and Poncelet's porism of inscribed triangles. (2) A self reciprocal figure, and the associated cubic surfaces.—L. **Godeaux**: Sur la representation analytique des congruences de coniques.—C. T. **Preece**: Dougall's theorem on hypergeometric functions.—W. L. **Marr**: A quintic locus defined by five points in a plane.—J. **Brill**: On the problem of three bodies.—C. G. F. **James**: Extensions of a theorem of Segre's, with their natural position in space of seven dimensions.—T. M. **Cherry**: The form of the solution of the equations of dynamics.—R. A. **Fisher**: Note on Dr. Burnside's recent paper on errors of observation.—C. G. **Darwin** and R. H. **Fowler**: Further examples of partition functions.—H. W. **Richmond**: Real twisted cubics which are geodesics on quadric surfaces.

DUBLIN.

Royal Irish Academy, June 25.—Prof. Sydney Young, president, in the chair.—A. C. **O'Sullivan**: Corresponding points on the curve of intersection of two quadrics. Corresponding points on the curve of intersection of two quadrics u, v are defined as pairs of points the tangents at which to the curve are generators of the same species of the same quadric $\lambda u - v$. There are three kinds of correspondence, each related to one of the three ways in which the roots of the discriminant of $\lambda u - v$ may be grouped. If four points lie in a plane they, with their correspondents of the three kinds, lie in fours on 64 planes, 16 planes passing through each point. There exists a correspondence between the lines joining corresponding points and the points of the quartic curve, so that from any proposition relating to the points a proposition relating to the lines can be deduced. This transformation is expressed in elliptic functions by a quadric transformation which is equivalent to one of the forms of Landen's transformation, thus giving a geometrical interpretation in three dimensions of Landen's transformation for real arguments.

PARIS.

Academy of Sciences, July 9.—M. Albin Haller in the chair.—Gabriel **Bertrand** and Mlle. S. **Benoist**: The nature of "celloisobiose." The celloisoboise of Ost and Prosiegel and of Ost and Knoth appears from its properties to be a mixture of procellose, described by the authors in a previous communication, and cellose.—André **Blondel**: The conditions of yield of generating valve lamps having a characteristic of the singing electric arc: the definition of their power.—V. **Grignard** and R. **Escourrou**: The tertiary methylheptenols: their catalytic hydrogenation. The product of hydrogenation varies with the catalyst (platinum black, nickel), and also with the pressure of the hydrogen. The best results were obtained with nickel working under a pressure of about 15 mm. of mercury.—Serge **Bernstein**: The best approximation of functions possessing one essential singular point.—Nikola **Obrechkoff**: A problem of Laguerre. F. **Selety**: A distribution of masses with a mean density zero, without centre of gravity.—Th. De. **Donder**: The synthesis of the gravific.—André **Kling** and Arnold **Lassieur**: Aqueous solutions. A sketch of a theory explaining the behaviour of water towards indicators and the hydrogen cell independently of the ionic hypothesis.—Pierre **Bedos**: Ortho-phenyl-cyclo-hexanol and the bromhydrin of 1·2, cyclohexane diol. Ortho-phenyl-cyclo-hexanol is the main product of the reaction between the oxide of cyclohexane and phenylmagnesium bromide. It would appear to be a stereoisomer of the compound of the same composition obtained by Braun, Gruber and Kirschbaum by the addition of hydrogen to ortho-oxydiphenyl.—Pierre **Jolibois** and **Chassevent**: The setting of plaster. An account of experiments on the maximum solubility of anhydrous calcium sulphate as a function of the temperature to which it has been heated.—Victor **Lombard**: The permeability of nickel to hydrogen. If d expresses the volume of hydrogen passing through the nickel plate of area 1 sq. cm. then it was found that at constant difference of pressure on the two sides of the plate, $d = a^t$: at constant temperature, the yield of gas $d = K\sqrt{P}$, where P is the difference of pressure.—Roger G. **Boussu**: Contribution to the study of supersaturation. Details of experiments with supersaturated solutions of potassium bitartrate and calcium sulphate.—L. J. **Simon**: The oxidation of graphite by a mixture of silver bichromate and sulphuric acid.—H. **Gault** and G. **Ehrmann**: The soluble cellulose-ether salts of the higher fatty acids. Hydrocellulose is treated with an acid chloride and pyridine in the presence of a solvent. Descriptions of cellulose distearate, dipalmitate, and dilaurate are given.—Max and Michel **Polonovski**: Escrolmethene and its alcoholate.—F. **Delhaye**: Relations between the orogenic movements and the great depressions of Central Africa. The *graben* of Lufira (Katenga).—Mlle. J. Boisse **de Black**: The mode of formation of a *frane* in Cantal.—Allyre **Chassevant** and **Chouchak**: The measurement of the degree of ionisation of mineral waters.—H. **Ricôme**: Growth and heliotropism.—Jean **Politis**: The mitochondrial origin of the anthocyanic pigments in flowers and leaves.—M. **Piettre**: The humus in the coffee plantations in Brazil.—M. **Aron**: The influence of temperature on the action of the testicular hormone.—A. **Desgnez** and A. **Bierry**: The action of Vichy water on the urinary reaction.—Jean **Camus**, J. J. **Gournay**, and A. **Le Grand**: Experimental diabetes.—M. **Lévy-Solal** and A. **Tzanck**: Puerperal eclampsia and the phenomenon of shock. Arrest by pilocarpine.—M. **Bazin**: Animal and human neoplasms.

Supplement to NATURE

No. 2805 AUGUST 4, 1923

The Ether and Electrons.[1]

By Sir OLIVER LODGE, F.R.S.

PRELIMINARY.

I HAVE been asked to speak on possibilities of research in pure physics, and I rejoice that attention has always been paid to the vital importance of pure science in an Institution the backbone of the work of which must be of a metrical character connected with industrial applications, and much of it necessarily subject to routine.

The main lines on which physics has recently and is still so rapidly advancing are well known. There is no need to direct attention to such inquiries as are the direct outcome of radioactivity, in its various forms spontaneous and induced: problems which range from atomic investigations like those which go on in the Cavendish Laboratory, through X-ray and ordinary spectrum analysis, down to the various devices of wireless telegraphy. In all these things there are among the members of the staff of the National Physical Laboratory, and on the Governing Body, more than competent advisers.

I must just deal with such ideas as have been occupying my attention of late. I have found it interesting recently to look up some forgotten remarks of my own—made soon after a National Physical Laboratory was decided on, but before it was founded—in the preliminary portion of a presidential address to the Physical Society of London on February 10, 1899, as reported in the Proceedings of that Society, vol. xvi. Part VI., June 1899. Among other things there referred to, is a suggestion by FitzGerald that circularly polarised light sent through an absorbing medium might constitute it a magnet—a discovery not yet made. I see there also a reference to a Blue-book of 1898 recording a Government conference about the founding of this Laboratory. Sir Richard Glazebrook has also kindly directed your attention to my address to Section A of the British Association at Cardiff in 1891, in which the foundation of a National Physical Laboratory was specially advocated.

[1] From an address on "Some Possibilities for Research in Pure Physics, especially on the Ether," delivered to the staff of the National Physical Laboratory on March 14. The first section of the lecture is omitted for lack of space. It dealt with possible research in boundary or overlapping regions of specific sciences, and on the relation between physics on one hand, and chemistry, physiology, and biology on the other. This section, and one giving further details about the possibility of a renewed attempt to detect or to disprove an ether flow along lines of magnetic force, will be published elsewhere.

PROPERTIES OF THE ETHER.

The question of what constitutes a distinction between physics and chemistry is difficult to decide, but in general it may be said that chemists deal chiefly with static relations and groupings, while physicists are more inclined to treat phenomena kinetically. Another clear distinction, at any rate at present, between these two sciences is that one deals with matter only, and the other deals with the ether also. It seems that the electric charge is the unifying or connecting entity between matter and ether. Uncharged matter appears to have no effect on ether at all. But its charged particles, or electrons, in so far as they quiver or rotate, do disturb the ether and generate waves in it. Moreover, if they revolve or travel, as by locomotion, they generate magnetism in it; and even when they are stationary, they generate in it or rather are inevitably accompanied by what is called electric force. That is, they appear to attract or repel each other from a distance. Furthermore, for some reason—which I and some others think to be residual electric or possibly magnetic attraction,—they exert over minute ranges the force known as cohesion, which again must be exerted entirely through the ether, since particles of cohering matter are not in contact. And again they exert, even at the most enormous distances known to astronomy, the minute residual force known as gravitation; which in the case of bodies of astronomical size amounts to a force of gigantic magnitude.

Light, magnetism, cohesion, gravitation,—all these are affairs of the ether, and are all studied in physics. A superstition has recently arisen that the ether is an exploded heresy, and is unnecessary; but that is an absurd misunderstanding. The theory of relativity says nothing of the kind. As a mathematical method it need not mention the ether, any more than Laplace in his "System of the World" felt that he need mention the Creator. He was entirely within his rights in ignoring the Deity; and so is a relativist in ignoring the ether; at least when neither attempts to philosophise on that basis. For ignoring a thing is not the same as putting it out of existence. Extinction is as impossible to us as Creation. We have to take things as we find them: and we find ourselves imbedded in ether and matter. So we had better make the best of it.

PRESENT KNOWLEDGE ABOUT ETHER.

How much do we know about the ether, and how much is it possible to ascertain? We do not know as much as we ought, but we know a few things; and we hope by further investigation to know more.

Unfortunately, the ether is a very perfect, elusive, highly-endowed substance, which makes no direct appeal to any of our sense organs. Accordingly, it is only investigated with some difficulty; and its properties are so different from those of matter that very elaborate and expensive arrangements have to be made in order to cope with it. Even when we have made those arrangements, it may decline to give an answer, and the result may be negative. Still, a truly negative result is something definite, and is better than nothing. But every positive result is of extreme value. Let us summarise the results we already know.

First of all, we know that the ether can transmit waves at a definite and finite speed of 300,000 kilometres a second. Next, that those waves are electromagnetic, with the electric and magnetic vectors at right angles to each other, and in the same phase. We also know that the superposition of related electric and magnetic vectors in the same phase results in propagation with the speed of light.

Then we know that light cannot be transmitted by conductors of electricity, which act like a solution of optical continuity. Furthermore, inside a transparent body light travels more slowly than in free space, showing that the ether is affected somehow by the neighbourhood of matter; the amount of this affection being sometimes called the refractive index, which is the measure of the retardation experienced by light, and sometimes, from another point of view, the dielectric coefficient.

We further know that if transparent matter is moved in the direction of the light inside it, a certain fraction of its velocity is added to the light—added of course algebraically. Thus demonstrating, not that matter has any power of conveying light—which it has not—but that some influence or reaction on the ether belongs to the matter and travels with it; that influence being just the one which effected the retardation and is responsible for the refractive index, the fraction of added velocity being, as surmised by Fresnel, $1 - 1/\mu^2$.

We also know, from certain experiments conducted by myself, that this property of matter does not extend in the slightest degree beyond its boundary; so that however fast matter is moving, light just outside it is not affected at all. Or, as we may express it, matter has no power of carrying the ether with it. The ether has nothing of the nature of viscosity. If a fluid at all, it is a perfect fluid. Not even if the matter is charged or magnetised does the influence extend beyond its boundary so as to affect the stream of light close to it. (See *Phil. Trans.* 1893 and 1897.)

Yet inside transparent matter the phenomena of light show that the ether must be modified in many ways, giving rise to all manner of crystalline effects —the optics of crystals—and the various phenomena of polarisation; especially that interesting one discovered by Faraday, that the plane of vibration is rotated, in one direction or another, by even non-crystalline and fluid matter when immersed in a longitudinal magnetic field: and those other phenomena discovered by Kerr, all of which may be summed up under the names elliptic and rotatory polarisation.

It is easy enough to say that light is retarded to a definite extent by transparent matter, but the complete theory of it is not so simple. Something about it will be found in the writings of Sir J. J. Thomson. All the phenomena of dispersion and anomalous dispersion must be taken into account if we would understand the inter-relation between matter and ether.

New Effects.

Not long ago the interesting phenomenon was discovered by Prof. Richardson that the act of magnetisation rotates a piece of iron, and a quantitative investigation of this delicate effect has been made recently by Prof. Chattock and Mr. Bates. I understand that a converse effect has now also been observed by Mr. Barnett, namely, that rotating a piece of iron magnetises it. I remember making an attempt to discover such a phenomenon long ago at University College, London; but I found nothing securely. Capricious and spurious effects were difficult to avoid, and I suppose I had not sufficient perseverance. We knew nothing in those days about electrons or their orbits, though we felt that there was something rotatory about magnetism; nor was it more than a suspicion that electricity itself might possess a trace of inertia, in addition to the recognised quasi-inertia of self-induction. Modern skill may have been able to overcome the difficulties inherent to such an experiment, but caution is desirable, since it is not clear why rotation should develop one polarity rather than another, if the atomic arrangement were truly random.

There is more to be got out of the original discovery by Richardson than has yet appeared—and I venture to predict that we have by no means heard the last of it. The Zeeman effect seemed small at one time; and if it be said that the Richardson effect could have been anticipated, I reply that Larmor anticipated the Zeeman effect; though it is true he did not expect the right magnitude, because the mass of the particle responsible for radiation was not then known. The quantitative relations of the Zeeman phenomenon clearly showed, for the first time, that the radiating particle was one of electronic and not of atomic mass.

I mention these two apparently disconnected phenomena together advisedly; for while the orientation or precession of electronic orbits in gases account for the Zeeman effect, the orientation of electronic orbits in iron accounts for the Richardson effect. Both are small, but the Zeeman effect is the smaller of the two; it needs the appliances of spectrum analysis for its detection. It is far bigger than it would have been if the atom had been the radiating element instead of the thousand-times smaller mass of the electron. As to the Richardson effect, it is surprising that it has been observed and measured at all, for the smallness (in mass) of the electron is no help to that; and the detected reaction is not something optical or etherial, but the gross movement of a mass of ordinary matter. Not much movement, truly,—quartz fibres must be used of course, and plenty of refinements,—but still a material movement is observed as the result of orientation of electronic orbits; and that is noteworthy. Reaction of radium from atomic projectiles was observed before, and reaction of radiometer vanes too; but alpha rays are atoms, and these

effects are connected with atomic bombardment; so in that respect they differ from the effects just mentioned.

I would liken the Richardson effect in some respects more to the Lebedew and Nicholls and Hull detection of the pressure of light, as suggesting an etherial reaction on ordinary matter.

Referring to this light-pressure; it is so small that Crookes failed to detect it, just as Faraday failed to detect the Zeeman effect with the appliances of his day and without a Rowland grating; but the most trivial fact, so it be a fact, is of enormous and may be of cosmic importance. Poynting invoked light-pressure to account for cometary and other astronomical results; and now Eddington calls upon it to sustain the Atlas-like burden of holding up the billions of tons of superincumbent material which constitutes the crust or envelope of a giant star. An amazing application of the (terrestrially) almost infinitely small.

Parenthetically, in using the term so-and-so's "effect," I do so under protest. This personal kind of nomenclature should be temporary, and not outlive the generation of discovery. This kind of naming began with either the Doppler or the Peltier effect, and was right enough when novel effects were few; but now that they constitute a multitude, we older folk are apt to get confused among the plentiful crop which the more fortunate youngsters are continually evolving. Prof. Richardson is entirely free from blame, for he calls his discovery a gyro-magnetic effect; which is explicit and satisfactory.

The Positive Electron.

Before leaving this part of the subject I should like just to direct attention to what I have written in Nature for November 25, 1922, p. 696, that we have not yet securely discovered the positive electron. The proton has to serve that function for the present, but what the constitution of the simplest known nucleus of an atom is, remains to be determined. Something is known about the proximate or apparent constituents of some heavier atomic nuclei, though not much, but nothing at all of the constituents of the nucleus of a hydrogen atom. It *may* be an indivisible particle so small and concentrated as to have a mass 1800 times that of a negative electron; but to me it seems unlikely that this is the right solution. It *may*, on the other hand, be built up of a stable grouping of hypothetical electrons both positive and negative,—each one being like a mirror image of the other. If so, it remains to be explained why the outstanding charge of all atomic nuclei is apparently positive, and whether that is accurately true. All I advocate is to keep the door open for further investigation, and to persevere with the quest of the positive electron by any methods that may suggest themselves.

Why negative electricity should differ from positive so greatly, or in any respect save in sign, is not at all clear; and it is difficult to understand how one of these entities can have been constructed out of the ether, without the simultaneous production of its opposite partner.

Electrical Theory of Matter.

The mechanics of the ether are not yet known; and until we have devised some system of mechanics which applies, not in a blindfold, but in a clear and lucid, manner to the behaviour of the ether, we must remain to some extent in the dark. Here, then, is scope for experiment. At present we are using ether waves to examine the properties of matter, the structure of crystals, the structure of molecules, and even the structure of the atom. But we must go on in due time to use these phenomena for an investigation of the ether itself. We know that movement of matter does not affect the refractive index nor the polarising properties of that matter. But we know that if matter is moving fast enough, it tends to carry some ether with it, and thereby adds to its own inertia to a known and predicted extent. We also know that inertia itself is a magnetic and therefore etherial phenomenon. The way in which J. J. Thomson, Heaviside, and Larmor have worked out the electrical relations between ether and matter, as regards inertia, changes of inertia with speed, and radiation consequent on acceleration, has been a marvellous achievement of our time, of which quite inadequate popular notice has been taken. Still there it is. They have laid the foundation of the Electrical Theory of Matter, and have opened up a way for our descendants to explain nearly all the properties of matter in terms of the ether, and possibly the very existence of matter itself.

We do not yet know how an electron is composed. We know still less—if that is possible—how a proton is composed. But that they ultimately will turn out to be etherial structures of some kind is possible and, as I think, probable.

Meanwhile we know that not only the mass of bodies, but their shape, is affected by motion through the ether; this was demonstrated by that great experiment of Michelson's, which I regard primarily as an experiment on matter by means of light, and not an experiment on light by means of matter. It may hereafter be regarded by a sensible though preposterous historian—that is, one who puts the cart before the horse—as the first and only verification of the Fitz-Gerald-Lorentz theory of modified electrical cohesion, or peculiar interaction between moving particles. It has been used as the foundation of the Theory of Relativity. But that is an ingenious offshoot or excrescence. I should like everybody to realise that the Electrical Theory of Matter had already accounted for nearly all the things which drop out so naturally from the theory of relativity: such as the increase in mass, the FitzGerald contraction as a reality, the Fizeau effect on light; even an extra revolution of the axes of a planetary orbit, unless gravitation itself is modified by motion. (See several Articles in the *Phil. Mag.* between August 1917 and June 1918, by Prof. Eddington, G. W. Walker, and myself; beginning with page 81 of vol. 34, and with conclusions summarised on pp. 143, 482, and 486 of vol. 35.) The Electrical Theory of Matter may conceivably be made to account for the two other as yet incompletely verified gravitational effects so brilliantly predicted by Einstein. But that remains to be seen.

Possible Experiments.

Limits of space will not permit me to deal here with the possibility of an experiment to determine whether there really is etherial circulation along magnetic

lines of force; attention may be directed, however, to papers describing my early attempts at such experiments, as partly described in the *Philosophical Magazine* for April 1907 and May 1919. In making experiments on the ether we must recognise that what we set out to look for we may not find: but we can also remember that careful and conscientious experiment, conducted with good apparatus, must lead us somewhere, and may result in a discovery exceeding in importance and interest any property we had set out to examine.

Kinetic Elasticity.

The contrast between the kinetic and the static mode of regarding things runs all through physics. Most physicists are imbued with the more fundamental character of a kinetic explanation, and never feel really satisfied with an explanation in terms of static or potential energy. Of the two kinds of energy, kinetic appears to them the more fundamental kind.

So, as we all know, Lord Kelvin tried to explain the elasticity of a spring balance, or any spiral spring, by means of gyrostats, or spinning tops. He was able to devise, at any rate theoretically, two concealed mechanisms, one of which was static and the other kinetic; that is to say, one of which contained a spiral spring with a protruding hook at the end, while the other contained a precessing system of gyrostats, also with a protruding hook. The observer was challenged to hang things on the hook, or to feel its recoil, and to say which was which. Or, in more general terms, Lord Kelvin endeavoured to devise a kinetic theory of elasticity. His famous theory of the vortex atom, in which he tried to explain some of the properties of atoms in terms of vortex rings and their collisions and interactions, was of this nature. It was extended by J. J. Thomson at an early date into almost chemical regions, in his early Adams' prize essay.

In his later life, Lord Kelvin was inclined to abandon this view of elasticity as regards solids; and his vortex atom declined to satisfy either him or others, on further development. But none of these ideas should be completely abandoned. In so far as they successfully illustrated any of the properties of matter, they are worthy of consideration. Although we now know that the atom is not a vortex ring, or anything like it, I would challenge any one to say the same of an electron. The electron has become the fundamental material unit: and what its constitution may be, we none of us know. It must be in close relation with the ether, and must ultimately, as I think, be explicable in terms of the ether. But the fundamental properties of the ether are too little known at present to enable this to be done. We cannot say whether the electron is to be explained statically as a knot or other geometrical configuration or strain centre, on one hand, or as some kind of circulating or vortex movement on the other. The constitution of the electron remains for discovery, in spite of all the work of Larmor on the subject in his brilliant book "Ether and Matter," and other papers imbedded in the *Phil. Trans.* If it should turn out that an electron can be thought of as a knot or any kind of static strain, then I for one feel that that cannot be regarded as an ultimate explanation, though a most useful approximate one, and that the strain will have to be resolved into or accounted for by some kind of etherial vortex motion.

Not only have the electric and magnetic forces belonging to an electron, respectively at rest and in motion, to be explained; but also the slight residual strain depending on the square of the charge, and therefore irrespective of sign, which we call gravitation, has in a complete theory to be explained also. For few can doubt, I think, that gravitation must now be regarded as a function of the electron and the proton, that it is not something which springs into being when these units are associated so as to constitute an atom of matter; it is unlikely that the tight packing of a large number of hypothetical positive and negative units in the proton could account for it. More likely gravitation will turn out to be an etherial phenomenon explicable in terms of the beknottedness which distinguishes the singular point of an electron from the rest of the ether. The rest of the ether is not affected by gravity, but possesses qualities akin to what in mechanics we call elasticity and inertia. Otherwise the unspecialised ether of space could not transmit radiation, or sustain a magnetic field—as we know it does. For it is necessary always to remember that though electric lines of force terminate on material units, most of their course lies in undisturbed ether: while magnetic lines of force do not terminate at all, but are always closed curves, surrounding electrons in motion, but themselves existing, I presume, wholly in the ether, and showing every sign of being essentially a kinetic phenomenon, demonstrative of inertia.

Inertia itself I see no way of explaining in any fundamental manner. It seems to be a property that we must postulate as existing in the ether,—a property akin to density; though it is true we can explain the inertia of matter—that is, of any material unit—in terms of the concealed magnetic fields inevitably associated with its motion.

To leave these more transcendental regions for the present, we may recall that although the kinetic theory of elasticity has hitherto failed to develop in connexion with solids, it holds perfectly for the case of gases. The elasticity or recoil of compressed air used to be thought of as analogous to the recoil of an elastic spring. But Waterston first, and then Joule and others—including especially Maxwell and Clausius and Loschmidt,—explained it brilliantly, together with many other of the metrical properties of gases, as the result of molecular motions and bombardment; so that it has become a familiar and elaborate theory —the Kinetic Theory of Gases. Hence, in that form of matter about which we know most, the kinetic theory of elasticity holds the field.

Radiation and Matter.

Now come a series of questions which it is difficult to formulate precisely because of our inadequate knowledge, and concerning which we must make the best of the hints which from time to time are afforded us by Nature,—questions which are mainly concerned with the nature of radiation, and with the interactions between ether waves and ordinary matter.

It is unnecessary to point out in the first instance that light is now known to exert pressure, and therefore to convey momentum. An advancing wave-front possesses momentum, which it can transmit to any obstacle which either reflects or absorbs it. If reflected, the pressure it exerts is double what it exerts when absorbed; all quite in accordance with common sense. But I rather want to concentrate attention on the state of things when the wave-front is advancing—it may be for hundreds of years—through so-called empty space. It carries with it a pressure equal to the energy per unit volume. If the Third Law of Motion is true without exception,—and it is surely politic to assume the truth of that law until it is negatived,—there must be a longitudinal stress in that stream of light, with a reaction on the source at one end and on the advancing wave-front on the other.

The source is always something material. Light can only emanate from an accelerated—that is, from a revolving or vibrating—electron. Hence, at that end the reaction has a material basis, in accordance with the customary experience that a line of stress must stretch from one piece of matter to another. But what happens at the other end? When it encounters matter, the reaction is exerted on that matter, and everything is plain sailing. But while it is advancing in free ether, what is it that sustains the reaction? We can only answer, the wave-front. The wave-front cannot sustain it statically. It can only do so by advancing at the speed of light. But it is remarkable and worthy of note that in this particular the advancing wave-front simulates one of the properties of matter, namely, the power of sustaining stress.

Now to me this is very suggestive. We do not know what precisely is the kind of motion occurring in the associated electric and magnetic vectors which are travelling with the speed of light. We do not know the kind of motion associated, more statically, with an electron. But the guess is almost forced upon us that possibly these two kinds of motion are not entirely distinct. We could not say that perhaps they are one, and not two; for there are certainly differences between them. One must advance; the other may stay still. But is it possible to regard one as a consequence, or as a generator, of the other?

The electron generates light.

Does light generate an electron?

(I am using the term "Light" in a very general sense, not limiting it to the physiological kind which excites the sense of vision, but including X-rays, and all other forms of short wave radiation.)

What do we know about the effect of this kind of radiation upon matter? We know that it can produce the irregular movements that we call heat, and also that it can stimulate chemical action. But the discovery of photoelectricity shows us that it may do more. It may fling out an electron, with a surprising amount of energy, dependent upon the frequency, that is, upon the wave-length, of the incident radiation. This is a hint not to be ignored. Nor is it ignored; and there must have been many speculations as to the kind of way in which it achieves this result. One would naturally suppose at first that it must do it by means of resonance, that is, by the accumulation of properly timed impulses, until an explosion occurs. But the evidence is, on the whole, rather against a resonance view; because the result seems almost independent of the intensity of the incident radiation, and to depend only on its wave-length. Nor does it seem as if a great length of radiation was necessary in order to produce the result: though this is a matter which requires further and more conclusive experiment. If a beam of light is interrupted and cut up into small sections—as might be done by a narrow slit in a very rapidly revolving disc,—would this intermittent light be equally effective? For if it is equally effective, the fact would tend against the continuous accumulation of a small synchronous disturbance.

I believe that some experiments have been made in this direction, and that the answer—so far as it goes—is that intermittent is as effective as continuous illumination, and feeble light as efficient as strong. The energy falling upon a minute surface in a beam of diffuse light is insufficient to account for the energy of the resulting effect, unless it is a trigger effect.

But this rather wants pressing to extremes. To cut up a beam of light into really short portions is not very easy. If a radial slit a millimetre in width is made in a disc a metre in diameter, revolving a hundred times a second, light sent through it is diluted and cut up into sections; but the length of each section is still about a mile, and accordingly would contain more than a thousand million waves,—which is amply sufficient for resonance.

However, the evidence so far is supposed to negative the resonance idea: so much so that it has been supposed that the wave-front is not a uniform surface, but a speckled one; that it is discontinuous; and that the amount of energy concentrated in one of the specks may be vastly greater than would be reckoned on the diffuse or continuous theory.

The idea of a speckled wave-front would have seemed to our scientific ancestors rather wild; though it must be remembered that Newton, with his Corpuscular Theory, was temporarily satisfied with something very like it. Nevertheless, the Corpuscular Theory had to be abandoned because of the artificial way in which it explained polarisation, and because it seemed to require that light should travel quicker inside matter than outside, instead of slower—as Foucault proved it to do,—and because there are real difficulties in explaining interference and diffraction, unless the wave-front is continuous.

However, it does not do to turn down a theory too readily and prematurely, merely because we encounter a few difficulties. No hypothesis is wild which has attracted the serious attention of J. J. Thomson, and other brilliant physicists, including—as I think we must—even Faraday; as evidenced by his "Thoughts on Ray Vibrations" ("Experimental Researches," vol. iii. p. 447).

Moreover, though these ideas, as we perceive them at present, may not be able to substantiate themselves, yet they are the outcome of observed facts; and it may yet be found that, in a modified and revolutionised form, they may contain elements of truth at present unsuspected.

Wilberforce Model.

It may be said that if we depend on the pressure of light as conveying energy, it is a longitudinal phenomenon; whereas an electron is probably a rotatory or rotational phenomenon. Or again, if we attend to the magnetic oscillation in the beam of light, and consider that the electric oscillation is separated from it, or neutralised, by matter, that still there is nothing of the rotational kind about it.

One answer would be that circularly polarised light clearly has a rotational aspect. Another and more fundamental answer would direct attention to the transition, or interchange, that may go on between a linear oscillator and a rotational oscillator when they are of the same frequency, or properly attuned.

In illustration of that, I would invite attention to the illustrative models constructed by Prof. Wilberforce, my successor in the chair of physics at Liverpool, which show that a continual interchange of energy between a linear vibration in one direction, and a rotational vibration in a plane at right angles, naturally goes on when the two modes are synchronous. Thus the energy alternately takes first one form and then the other; and then back again, without intermission.

Of course the dynamics of the model is thoroughly understood, and Wilberforce himself has explained it, that is, has recorded the relevant equations;[2] and in that sense there is nothing puzzling about it, though its behaviour can be made to look rather paradoxical. But I feel that there is some meaning underlying the possibilities here indicated, which are not yet completely exhausted, and that they may, when more deeply considered, throw some light upon the interaction between electricity and magnetism—if that should still be necessary,—and possibly on the interaction between ether and matter, and perhaps between waves and electrons, where more information is certainly necessary. At any rate, I regard the behaviour of the model as suggestive, and am content for the present to direct attention to it, from this point of view.

Origin of Electrons.

Let us assume, then, for a moment that there may be some truth in the idea of a discontinuous wave-front. To what are we led? I should reply, that the motion in a wave-front seems more akin to the kind of motion that constitutes the discontinuous and isolated speck that we call an electron; and that the actual generation of an electron by means of light is not an altogether impossible idea.

So I repeat the question:

An electron suddenly set in motion generates light: does light when it is suddenly stopped generate an electron?

Sir William Bragg has often directed attention to the singular relation existing between X-rays and beta radiation. The impact of a beta particle emits X-rays. The impact of X-rays emits a beta particle. The energy of the original and the excited beta particle are so closely proportional as to be practically identical. It is as if the same beta particle, that is, the same electron, had gone out of existence at one place, and been recreated at another, the intermediate link being constituted by specific radiation of a perfectly definite wave-length.

There is no need to *assert* that one particle has gone out of existence and the other come in; and yet we know of no reason for denying it. It may have to be denied, but I think it wise to keep an open mind on the subject, however bizarre the notion may be. There are strange relations between energy and matter now coming to the front. Matter contains intrinsic energy, as if it were something circulating with the velocity of light. There must be some meaning in this. The ratio c^2 between matter and energy is not to be ignored.

Somehow or other the ether possesses inertia. It must, or it could not sustain magnetism, or account for the increase of inertia due to motion. The ether also contains an intrinsic and characteristic velocity, which is perfectly definite. It is known that the vibrations of vortices, and the speed at which a vortex medium can transmit transverse waves, are closely connected with the constitutional velocity of rotation. The two velocities are in fact equal, or connected by a numerical factor, of a magnitude which some theories make $\sqrt{2}$, but other theories make unity. In any case the numerical factor is not far from unity. We are justified in supposing that if the ether is full of circulatory motion, that motion must be practically the velocity of light. In that case, the fundamental nature of matter would appear to be giving up its secret; and the relation between matter and energy would be explained.

There does not then seem any insuperable difficulty about hoping that some future discovery will be able to generate matter, or at least to generate an electron, by aid of X-rays or other form of radiation. I can dimly conceive a theory of light which, when its advance was stopped, should terminate not in the irregular jostle called heat, but in the regular circulation or vortex motion that we call an electron. The intimate relation between energy and frequency associated with the quantum seems to me to negative the mere irregularity of thermal agitation, and to suggest something quite regular and constitutional.

We can go further, and can reckon how much matter would be generated by a given amount of luminous energy, if none of it were wasted as heat. A beam of ordinary sunlight ten centimetres square shining continuously, and supposed to be all converted or interpreted as matter, would generate a weighable amount, namely one-tenth of a milligram, in seventeen years.

The density of sunlight near the earth is equivalent to 2×10^{-15} gram per second per square centimetre. So if it were interpreted as matter, the earth would catch 80,000 tons of it per annum. Of course, some of it is wasted. Only radiation of the right frequency is effective, just as only energy of the right frequency is generated by a metrical impact. A lot of the radiation may be due to irregular jostling, and this portion when absorbed may result in heat. But it is the more precise kinds of occurrence which are instructive, and which must inevitably attract attention.

I know that the Bohr Theory of the Atom seems at first against these speculations. Electrons appear

[2] *Phil. Mag.*, October 1894.

to jump from one orbit to another, and thereby give out a certain quantum of energy. But this may be a supplementary and not a contradictory statement. What makes the electrons jump? Which electron jumps out? Sometimes it is from the K ring, sometimes from the L ring; and so on. All those things may be known. But still I ask, What started the disturbance? If an electron is generated by the impact of light, it does not follow that that particular electron is the one ejected. Its entry may be the means of ejecting another. Somehow or other the atom must get another, in order to restore its constitution. There are doubtless many ways in which a strayed electron could be recaptured; and I venture to suggest that our speculation suggests one of them.

Possible Utilisation of Waste Radiation.

There is an immense amount of radiation travelling about space. The whole amount of solar radiation is portentous. The fraction which the earth catches, though terrestrially so important, is but a minute fraction of the whole—less than the two thousand millionth part,—and it seems to have been going on for hundreds of millions of years. The radiation from many of the stars is greater. What becomes of all that radiation? Is it all waste? Space is so enormous that though thousands of millions of suns have been pouring out their energy for thousands of millions of years, space is no warmer. The ether is not warmed by it: the ether does not absorb it. The ether is perfectly transparent. Yet our instinct rebels against the idea that all this radiation results in nothing. Sir W. Siemens speculated as to its possible concentration by total reflection at an ether boundary. But I cannot imagine an ether boundary. I can more readily imagine that light results somehow in the generation of matter; and that there is a reciprocal interaction between matter and ether waves; so that each is generated by the other,—a sort of constant and perennial interchange.

Electrons have come into existence somehow. The subject of origins usually lies outside science. The origin of matter is as beyond our ken as the origin of life; and yet people speculate about the origin of life. Some highly estimated men of science *hope* at any rate that some day the chemistry and physics of life may be so far understood that a highly complex assemblage of organic molecules may simulate and perhaps adopt its functions. I see nothing inconceivable in this. Life has originated somehow; and if we can get to understand anything about its origin, the effort is legitimate. It may fail; but it would be a very superficial view of religion which resented its success. Mind dominates matter; and the mind of man is not altogether of a different order from the mind of the Creator. But this is a subject on which I could say more on a more suitable occasion. I only say thus much now in order to repel any idea of impiety in speculating on a possible origin for matter.

Hypothetical Conversion of Radiation.

The possibility that a small body may gradually grow in mass under the influence of an etherial transformation, does not seem one to be scouted without proper examination. The amount of matter scattered about in space is by no means inconsiderable, and the problem of its origin has never been attacked. Given matter, the origin of radiation has been more or less solved. But, given radiation, the idea of its conversion into matter has not, so far as I know, been mooted. Possibly the idea is erroneous. But interactions in Nature are so frequent, and the interrelations between ether and matter are so ill understood, that I think we should not shut our eyes to the possibilities of some reciprocal interaction, even of a generative kind.[3]

Sometimes I see the difficulties of the hypothesis; sometimes I feel impressed with a sort of probability about it. It is easier to see the difficulties than the probabilities. But the relationship between energy and matter—connected as they appear to be with the second power of the characteristic ether velocity, and with the conception of an intimate fine-grained rotational structure for the ether—is not a hint that should be too lightly ignored or neglected.

Electrons build up matter. What builds up electrons? They are somehow intimately connected with the ether; their motion through it displays to us the phenomenon of magnetism; and their acceleration generates waves. So far, we are on firm ground. When we come to the converse or reciprocal relations, we have but few facts to stand on. But the emission of electrons by means of light is one of them; and the bearing of this fact, until it is properly understood inevitably justifies speculation.

Previous Guesses.

When I say that the idea of reciprocal conversion has not been mooted, I am going beyond the facts. In Loring's "Atomic Theories," page 80, I find the following sentences:

"Thus it would seem that the energy phenomena are reversible, so that the radiation is as it were convertible into moving electrons and moving electrons are convertible into radiation. It is of course only the energy which is thus convertible. The mechanism of conversion is not, however, known."

Again, in Millikan's book "The Electron," when speaking of Barkla's discovery of the remarkable absorbing property of matter for X-rays, he says:

"It will be seen from these photographs that the atoms of each particular substance transmit the general X-radiation up to a certain critical frequency, and then absorb all radiations of higher frequency than this critical value. The extraordinary significance of this discovery lies in the fact that it indicates that there is a type of absorption which is not due either to resonance or to free electrons. But these are the only types of absorption which are recognised in the structure of modern optics. We have as yet no way of conceiving this new type of absorption in terms of a mechanical model."

Sir William Bragg, in Nature (1921), vol. 107, p. 79, with reference to the experiments of Duane and Hunt, says: "Exactly how this strange transfer of energy from one form to another takes place we do not know: the question is full of puzzles." He has several times urged the extraordinary character of the fact that a stream of radiation excited by the

[3] Cf. letter in Nature, May 26, 1923, p. 702.

impact of one electron, after travelling a long way and becoming greatly enfeebled, can eject another electron with the same or nearly the same energy as the first. Facts such as these have suggested the discontinuous nature of a wave-front, and the actual concrete existence of discrete tubes of force, which are apparently analogous to, or suggestive of, vortex filaments in the ether. Again, there is the fact that the electrostatic potential energy of a charge is similar to what the equivalent mass would possess if it were moving with the speed of light. Also, *à propos* of this, I understand that Sir J. J. Thomson has expressed himself thus:

"When the energy of a system passes from kinetic into potential, there need be no transformation of fundamental energy, but merely the flow of a mass-producing material, with its intrinsic kinetic energy, from one position of space to another, under the guidance of the lines of electric force."

In accordance with a few other physicists, Thomson has been led to postulate a fine-grained structure for the ether, which I think rotational, but which he speaks of as particles. He suggests that mass is made up of identical particles all of the same kind, very small compared even with an electron, moving with the velocity of light, and subject only to a deflecting acceleration, not to any change of energy; the mass and energy of each particle being constant, but their distribution depending on the number or concentration of lines of force, each line being as it were anchored normally to positive and negative electrons, but capable of being thrown by motion into loops or closed curves, which would then move away with the velocity of light and constitute radiation. Wherefore it would follow that emission of radiant energy must be accompanied by a diminution in the mass of the radiating body.

The converse, therefore, that absorption of radiant energy might be accompanied by an increase in mass, almost naturally follows.

My presidential address to the Physical Society of London on the subject of opacity, that is, on the orthodox theory of absorption generally,—electrical as well as optical,—is contained in the *Phil. Mag.* for April 1899, and also in the Society's Proceedings; in the latter place it is preceded by preliminary matter not irrelevant to the present discussion.

Mechanism of Absorption and Emission.

To understand the mechanics of absorption we can learn from the mechanics of emission. In a wave the electric and magnetic vectors are simultaneous; that is, the electric and magnetic displacements exist together, superposed. At a source they are only coexistent in space, not in time; one succeeds and gives rise to the other, with successive alternations. A source may be at rest, and is merely an alternator: a wave is necessarily in motion. The relative phases of electric and magnetic oscillations in the neighbourhood of a source determine the fact and the direction of motion at each locality. Combined in one phase they expand or advance, combined in another phase they contract or recede; all this is known to occur near the source, that is, near a Hertz vibrator. In that region, within a radius of $\lambda/2\sqrt{\pi}$, the etherial disturbance oscillates to and fro; and beyond that range a portion of the energy acquires its locomotive character, and sets out with the velocity of light.

Shall not the converse take place when this speed of propagation is annihilated, and the ether disturbance is reduced to locomotive rest, within a similar range near an absorber? In that region the simultaneous electric and magnetic disturbances would be separated, and converted into a stationary oscillation, by a process inverse to that of radiative emission.

Considerations of this character are indicated by me more quantitatively in the *Phil. Mag.* for June 1913, pp. 770-788, and in February 1920, p. 173; also in April 1921, pp. 555-557, where I endeavour to associate the ultimate fate of radiation with a kind of Einsteinian gravitational theory. It there turns out to be necessary to examine electrically the essential nature of absorption; and the illustration or analogy with a Hertz vibrator, as either source or sink, is employed. I return to the subject in June 1921, p. 943, and again in July 1921, pp. 181-183; though in the last paper the chief point is the disintegration of atoms which is to be expected at a certain calculated very high temperature—such as has since been considered by Prof. Eddington likely to occur in the interior of giant stars.

Eddington has taught us—at any rate hypothetically—that in the interior of giant stars, where the temperature is excessive and the radiation powerful beyond easy imagination, the substance of the star is distended, blown out, supported, as it were, by radiation bombardment, as the skin of a football, or an india-rubber tyre, is distended by the molecular bombardment of the air inside. He has further speculated, so I understand, that the interior of these stars may constitute a laboratory in which the more complex atoms can be built up,—those same heavy atoms of which we have now at length begun to witness the breaking down, under the operations of spontaneous radio-activity. There cannot be breaking down everywhere: there must be building up somewhere. We do not yet know what can be accomplished under conditions of extreme heat and pressure,—nor, I may add, under conditions of great pressure combined with extreme cold.

It may be said: the analogy fails, since what I am trying to suggest is the generation of electrons, and we nowhere know of the breaking down of electrons. That is true: we do not know either of their breaking down or their building up. It may be that we shall discover the untying of an electron first; or it may be that we shall discover a tying-up first, and the untying later. Or it may be that, once tied, they are permanent. Or of course it may be that they cannot be tied. But these questions seem to me all open. The time for discovery is not yet; but he would be rash who would say that discovery in any particular region is impossible. If there are any clues, it is the privilege and indeed the duty of science to follow them up. If the clues are imaginary and useless, then open discussion will demonstrate their futility. But if we can see any distance, however dimly, into the unknown, then sooner or later we may be sure that pioneers will explore those dim regions until they are illuminated with the searchlights of systematic knowledge.

Pensionable Teaching Service.

IN our issue of November 18, 1922, we published a leading article dealing with the principles of Circular 1286 issued by the Board of Education. That circular attempted to define what was a "Full-Time" Teacher within the meaning of the Superannuation (Teachers) Act of 1918, and the attempt was by no means successful in so far as it applied to teachers of experimental science and teachers of technology generally, and particularly to teachers of advanced subjects in Technical Institutions. In the article referred to we pointed out the salient defects of the proposals, and we are pleased to record that in Circular 1311 of the Board of Education now before us there are not only some modifications but also some "explanations" which in themselves modify the original proposals considerably and suggest that Full-Time Teaching Service will be determined on broader and more knowledgeable principles than were indicated in Circular 1286.

In the new circular—we wonder, by the way, why it was not issued as a "supplement to Circular 1286"—the Board of Education states that it will apply the principles set out in the original circular, subject to the modifications and explanations indicated. These modifications go far to meet the objections raised in our article referring to Circular 1286.

The Board makes it clear that the 30 hours suggested as a weekly minimum (for 36 weeks, or the equivalent) were intended to include not only the hours of actual teaching but also hours devoted to subsidiary duties entailed by actual teaching; that actual teaching covers not only class teaching in accordance with a regular time-table, but also the supervision of preparation and tutorial work with individual pupils or small groups of pupils; and that the subsidiary duties to be taken into account are not limited to those which are performed on the school premises, since in many cases some of them can be performed more conveniently—and, we may add, more efficiently—elsewhere. Those explanations should help to round off many sharp edges of the parent circular.

There is also a more definite statement in respect of relief from actual teaching hours for heads of departments in Technical Schools and for assistant teachers in secondary and other schools who are charged with substantial duties in organising particular subjects or in organising features in the corporate life of the school. This is only right, and we are glad to see it definitely pronounced.

In clause 7 of the original circular there was a reference to research work which we considered to be very unsatisfactory. The Board now states that time spent

in instructing students in the methods of research will be regarded as forming a part of the teaching. Further, it is stated that research work which enters into the actual preparation of lessons to advanced students will be properly regarded as a duty subsidiary to actual teaching.

On the whole, then, it may be said that the new circular is more reasonable and more justly favourable than the old. We still feel that teachers in Technical Institutions may be penalised if their full-time service is to be judged by the same standard of actual teaching hours as that which normally obtains in Primary and Secondary Schools. We admit that the circulars do not say they will be so judged, but, on the other hand, there is no statement, direct or implied, that the same standards exactly will not be applied. That would be extremely unfair, and extremely bad educationally, to those teaching subjects which involve experimental demonstration and laboratory preparation, and to those teaching advanced subjects. A definite statement on this point would have allayed anxiety on the part of many who are approaching the pensionable age.

Further, most of the work done by full-time teachers in Technical Institutions is evening work, and this work is necessarily more intensive, and involves not only a heavier strain in the actual teaching process but also much more complete preparation work than is required for corresponding day work. We regret that this has not been recognised in the new circular, for even though the officers of the Board may recognise it and act upon it, it does not seem fair either to the teachers concerned, or yet to the Principals and Education Authorities, that no definite pronouncement is made on the subject.

Finally, we cannot help feeling that Circular 1286 should not have been issued officially before it had been submitted to representatives of the authorities, governing bodies, and teachers concerned. The Board stated in the first paragraph of that circular that though it contemplated the application of the principles set out, it would be glad to consider any observations by a certain date before arriving at a final decision. The result of the observations is shown by Circular 1311; but surely it would have been very much better had the revision been made before the official issue of the first circular. As it is, there has been much difficulty and misunderstanding, and in some cases these provisional principles have already been acted upon and, in the light of the supplementary and explanatory circular before us, acted upon wrongly. We also feel that it would have been better to have cancelled Circular 1286 entirely and to have issued a new one amended on the lines of Circular 1311.

Map-making from Air Photographs.

Generalised Linear Perspective: Treated with Special Reference to Photographic Land Surveying and Military Reconnaissance. By J. W. Gordon. Pp. xvi + 184. (London, Bombay and Sydney: Constable and Co., Ltd., 1922.) 21*s*. net.

DURING recent years much attention has been paid to air-photography as a means of surveying; the present developments of the subject being chiefly due to the varied experience which was gained in the War. The method is still on its trial. There are certain conditions under which it promises to be successful, but no peace-time surveys of any importance have yet been carried out on this system. It is likely to be found of value in flat countries, and for maps on medium scales. Air-photo surveys have been suggested for the mapping of deltas, such as those of the Ganges, the Niger, and the Irrawaddy, and for the surveys of large native towns. The suggestion, made a few years ago, to map a hilly West Indian island in this way, was, probably wisely, "turned down."

The subject is thus, so far as concerns peace-time surveys, in a tentative stage, and any original contribution to the theory is most welcome. Mr. J. W. Gordon has made such a contribution in his book entitled "Generalised Linear Perspective." He gave a demonstration of his methods at the British Museum on March 25 last, and they have been described in popular terms in the *Times*. His ideas are thus being made well-known.

The main object of his investigation is to find a direct and simple system of converting an "inclined" air-photograph into a map or plan. In the most general case a photograph is taken in the air, at an unknown height above the ground, of country with unknown undulations and hills; the camera is tilted at an unknown angle and the direction of the tilt is also unknown. Nowadays, however, thanks to the insistence of the Air Survey Committee, it may be expected that the focal length of the lens will be known in every case, and also the position of the optical centre of the photographic plate.

The first step in Mr. Gordon's investigation is to choose a horizontal reference plane on which the plan of the ground is to be projected, at a distance from the nodal point of the lens equal to its focal length—a useful simplification, which, however, determines automatically the scale of the plan, so that photographs taken at different heights will be plotted on different scales.

Mr. Gordon introduces us to a new terminology, puzzling at first, and not always very clearly explained, but legitimate. It is necessary to learn the

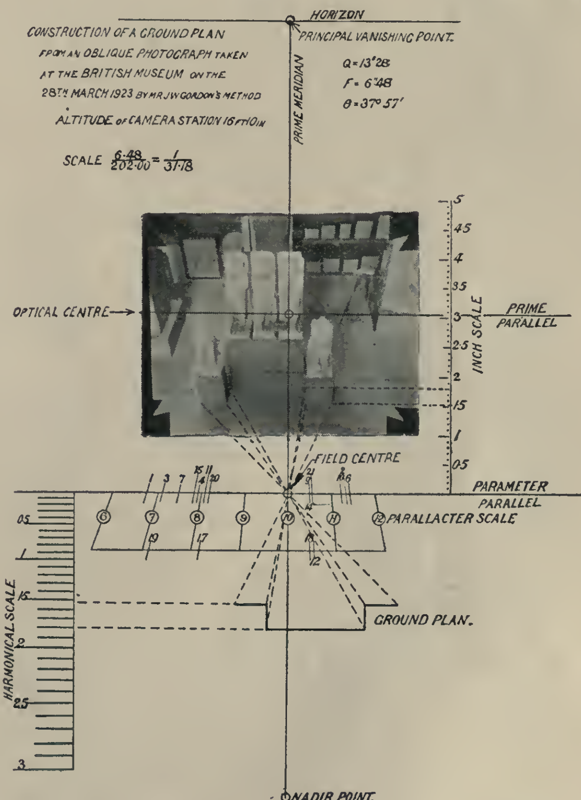
meaning of such terms as air-foot, margin, margin parallel line, carto-photo-field, parameter parallel, and so on. By taking measurements from the horizon on the photograph and from the "margin" on the reference plane (the margin being the intersection of the reference plane with a plane through the nodal point parallel to the plate), the invariable relation is obtained $H/p=p/h$, where $p=F \sec \theta$, F being the focal length, θ the tilt of the optical axis measured downward from the horizontal, h the distance measured to any point in the photograph from the horizon, and H the distance from the "margin" to the projection of that point in the reference plane, these distances being measured in the principal plane. Such distances have thus the reciprocal relation that if one set, say in the photo plane, is expressed as an arithmetical series, the other set in the reference plane will be expressed as a harmonical series.

Along the line of the intersection of the photo plane with the reference plane all magnitudes have, of course, the same value; and it also results from the perfect similarity of position of the two planes that, at the point on their intersection where it is cut by the principal plane (the vertical plane containing the optical axis), angles on the reference plane are correctly represented on the photograph. This point, which is sometimes known as the "isocentre," is called by Mr. Gordon the "field centre," and, as he remarks, this property of the identity in the two fields of any angle located in the field centre is the fundamental law of the perspective of angular magnitudes. The field centre is thus an appropriate origin for polar co-ordinates.

Let us now imagine the photograph to be hinged along the line of its intersection with the reference (or map) plane, and let it be turned round on this axis until it is in the map plane. The hinge (parameter parallel) is a line on which all lengths are truly represented in the photograph, and the field centre is a point in this line at which angles are truly represented. Distances measured at right angles to the hinge are connected by the expression $H/p=p/h$. For distances measured parallel to the hinge, we have $Y/y=p/h$ where Y is the ordinate of a point on the map, y that of a point on the photograph; or $Y/y=(X+p)/p$, where X is the abscissa on the map plane, measured at right angles to the hinge.

To make use of these expressions we must fix on the photograph the position of this hinge line, which is parallel to the line of the horizon; and to do this we must draw the horizon. The distance between the hinge line and horizon is p. To fix the horizon, Mr. Gordon rediscovered, in the course of his investigation, a solution which he afterwards found had been given by Brook Taylor, of Taylor's Theorem, two hundred years ago. Thus, let there be three points in a line in the reference plane (or cartographic field), and let the known length of one segment be a and of the other b, the line lying in any direction. Let A and B be the lengths of the representations of these segments in the photograph. Then the distance, V, from the intermediate point of the three, on the photograph, measured along the given line, to the horizon, is $(a+b)AB/(aB-bA)$. This gives one point on the horizon and a second divided line will give a second point, so that the horizon can be drawn on the photograph.

Mr. Gordon also points out that it is possible, in a similar way, to identify the nadir point on a photograph, by making use of a vertical line on which three points have been marked at known distances from each other. From the nadir point, a line drawn through the optical centre, at a distance $2F/\sin 2\theta$ from the nadir point, gives the position of the principal vanishing point.



The accompanying illustration will serve to give an idea of the lines made use of by Mr. Gordon in constructing a plan from an oblique photograph. The method used was not precisely that which would be employed in survey work, but the diagram indicates the general principle. The height of the nodal point of the lens was 16 ft. 10 in. above the floor; the focal

length was 6·48 in. The optical centre of the photograph was known. In place of measuring the tilt, this was determined from the photograph; the joints in the floor gave the principal vanishing point, and the vertical lines the nadir point. If the distance between these two points is Q, then the angle of tilt $=\frac{1}{2}\sin^{-1}2F/Q$; in this case the tilt worked out at $37° 57'$. The distance of the parameter parallel and field centre from the principal vanishing point is p. If an upright arithmetical scale, measuring from the parameter parallel, is drawn alongside the photograph, this will be represented on the plan by a harmonical scale. Or, by computation, if h is the perpendicular distance, from the horizon, of any point in the photograph, the distance of the representation of this point, measured from and at right angles to the parameter parallel, will be $p(p-h)/h$. The intersection of parallels so obtained with rays drawn through the "field centre" will give the positions of the points on plan.

So far, the system is essentially a point by point method of plotting. It will, no doubt, often be found of real value, and the neatness and simplicity of the few calculations required recommend it, especially in those cases in which the plate is considerably inclined to the horizontal. It is not so convenient when the plate is nearly horizontal, and it would be a mistake to suppose that it enables photographs to be converted into plans which could not have been so converted by the methods used before its publication. The data required remain the same. The method has the minor disadvantage that the plotted plan will depend for its scale on the height of the camera, so that a mosaic of photographs will give a series of plans on different scales. But this is not an important objection.

Mr. Gordon's book is somewhat troublesome reading, and the student will probably find the clearest explanation of his methods and terminology in the chapter entitled "Recapitulation." But the book contains original matter and will take its place in the list of authorities which those interested in the subject must study.

Mr. Gordon states in his preface that recent developments of methods of military reconnaissance have given "an urgent call" for a generalised system; he writes of "the authentic rule which the soldiers of 1915 so urgently desiderated"; he states that he provides the solution of the mathematical problem "that grievously vexed the soldiers during the years of the Great War"; and he indicates generally that, in his opinion, the want of a knowledge of Taylor's rule, rediscovered by him, prevented the survey staffs of the armies from making effective use of air-photographs in the construction of military maps. This does not do justice to the work of the survey staffs. The writer of this notice is satisfied that if Mr. Gordon's book had been available during the War, it would have made no material difference. Mr. Gordon provides a new method of plotting; but several other thoroughly sound methods were in use.

No difficulty was, as a fact, experienced in converting air-photographs into plans by the methods actually used. It is not the case that oblique photographs were avoided on account of any supposed difficulty in making use of them. This is a mistaken idea. Photographs departing considerably from the horizontal were, in general, avoided, because it was necessary to get vertically, or nearly vertically, over the enemy, to find out what he was doing and to avoid the interference of cover. The photographs so obtained, although taken on plates that were only inclined to the horizontal some 3° or 4° on the average, were not treated as plans, but were converted into plans by perfectly orthodox methods. There is an admirable exposition of the matter by Lt.-Colonel M. N. MacLeod entitled "Mapping from Air Photographs," published by H.M. Stationery Office. All who are interested in the subject may be advised to read this. They should also read Mr. Gordon's instructive book, and they will then see that there are several ways of killing this particular cat.

Two other matters call for special comment, namely, contouring from air-photographs and the use of a vertical base. As to the first, the theoretical difficulties are not formidable, but the practical difficulties are, and neither Mr. Gordon nor any one else has yet properly solved them. At present Mr. Gordon's suggestion is as good as any, and that is to plot two maps of the same piece of ground from two different positions of the aeroplane, and determine the heights, point by point, by means of the varying parallaxes. This agrees with the advice of Lt.-Col. MacLeod, which is to prepare prints of two photographs, separately taken, "rectified" to a chosen horizontal plane, and from one of them to make a tracing which can be superimposed on the other, for comparison of parallaxes. But even this method will fail when the points are not visibly marked, and would be inapplicable to the contouring of an ordinary hill-side. Perhaps something might be done by stereoscopic plotting from two parallel plates simultaneously exposed from the extremities of the wings of an aeroplane.

With regard to the use of a vertical base, Mr. Gordon points out that it is theoretically possible, given, in the oblique photograph, a vertical line which has three points marked on it, at known distances from each other, to determine the nadir point on the photograph, and, the optical centre being known, the tilt and parameter parallel can be found. But the practical

difficulty of arranging for such a vertical line to appear in the photograph would appear to be considerable. Ropes suspended from small balloons are liable to be deflected from the vertical by local air movements, and the system would involve additional apparatus. The suggestion is an ingenious one, however, and deserves to be tried.

It should be noted, in conclusion, that recent[1] experiments by Prof. Melvill Jones and Maj. J. C. Griffiths have shown that it is possible to fly on such an even keel that the photographic plate shall seldom be inclined to the horizontal as much as 2°. This would result in linear errors, on the uncorrected photograph, of less than $1\frac{1}{2}$ per cent. In many cases this class of plotting error can be permitted for detail, and in such cases no knowledge of, or correction for, tilt would be required, and all that would be necessary would be to know the length of one line on the ground to give the scale. There would be a great saving of time and expense in plotting the map and in fixing ground points, and, for the more rapid kinds of reconnaissance, in flat or undulating country, progress may be hoped for in this direction.

Light and Health.

Heliotherapy. By Dr. A. Rollier. With the Collaboration of Dr. A. Rosselet, Dr. H. J. Schmid, Dr. E. Amstad. (Oxford Medical Publications.) Pp. xxii + 288. (London: Henry Frowde and Hodder and Stoughton, 1923.) 25*s.* net.

ALTHOUGH it has long been known that certain radiations have a powerful action on physiological processes, it is only in recent years that much attention has been given to the subject as it affects the higher animals. Apart from the mechanism of carbon assimilation in the green plant, our eyes have been mainly directed to the lethal effects of ultra-violet rays, and, more recently still, to those of X-rays and of radium. The author of the book before us was one of the first to appreciate and to make practical use of the *beneficial* action of sunlight. Dr. Rollier's work at Leysin has been made familiar to readers of Nature by the recent lecture given at the Royal Institution by Dr. Saleeby, and the reviewer cannot do better than refer those who wish for further information, with abundant and deeply interesting illustrations, to this translation of Dr. Rollier's book. Forewords are contributed by Sir Henry Gauvain and Dr. Saleeby, while special chapters are included on the scientific basis by Dr. Rosselet, on the use of X-rays in the control of the progress of the treatment by Dr. Schmid, and on the adjuvants of heliotherapy by Dr. Amstad, who also adds a chapter on non-tuberculous diseases.

The book itself is a most fascinating one and will be found full of interesting details, not merely of clinical nature, but of value to the student of science, art or morals. It should have a wide circulation, and the only criticism that I am inclined to make is that the price seems rather high. I refer to this now in order not to end on a discordant note. It is difficult to see what might be the cause of this high cost, and it is to be feared that it may tend to restrict the sale of a book which should be in the hands of everyone who has at heart the happiness of his fellow-men, and especially of those who love children. I wish particularly to direct attention to the wide general interest of the contents, because the title might give the mistaken impression that it is a purely medical work.

The scientific reader will notice that we have much to learn as to the physiological action of light, and it will probably serve the best purpose if I devote the space available to a brief reference to the facts brought out by Dr. Rollier's work and to the gaps which await the results of further investigation, much of which can be done in the laboratory.

In the first place, we must distinguish between the effects of rays of different wave-lengths. In rickets, it is a limited region of the ultra-violet that is effective; in tuberculosis, we have no precise knowledge of the important region, except that the heat rays of long wave-length have to be guarded against. The necessary exposure cannot be tolerated except under the cooling influence of alpine air or of sea-bathing. Recent work tends to show that the rays of the red end of the spectrum may neutralise the benefit of the shorter wave-lengths. There is scope for investigation of the action of optical sensitisers, when atmospheric conditions cut off the active rays. The red algæ give us an example to follow. It is also clear that exact measurements and records are needed of the rays of various wave-lengths present in the sun's light in different places and at different times of the year and day.

Next, we may note that Dr. Rollier has from the first been aware of the fact that the direct action of the rays on a diseased organ is not what is required. Exposure of the skin in any situation suffices. It is natural to draw the conclusion that some photo-chemical product is sent from the skin into the circulating blood. But we have as yet no actual proof of this, and there are other possibilities which cannot be entered into here. In any case, we are shown that the skin has some important functions hitherto unappreciated.

Then there is the remarkable fact that it is only those individuals whose skin takes on the well-known brown pigmentation after exposure to the sun who

react rapidly. We do not know the meaning of this—whether it is merely an unessential reaction which is associated with other characteristics of the individual, whether the brown pigment is an optical sensitiser, or again whether it is a screen to cut out injurious rays.

A further question requiring more investigation is the increase in oxidative metabolism. There may be reflex effects to muscle, or a direct result of warming of the blood (Sonne), or it may be simply a reaction to the cold air. It appears that the muscles of tuberculous patients may grow in size and firmness, although they may be but little used.

The general effect of the treatment is not to be overlooked, especially in the case of children brought into bright and interesting surroundings.

Although it is in the direct cure of disease that the most striking effects of sunlight are seen, it is impossible to believe that the physiological processes at the basis of these effects play no part in the prevention of disease. Dr. Rollier has an interesting chapter on his "École au Soleil," established for children predisposed to tubercular disease. Exposure to sunlight must, moreover, be of the greatest importance in maintaining normal health—a fact far too little taken to heart.

There are many points of practical importance brought to our notice by this book. I may conclude with mentioning two of these. Dr. Rollier shows that pulmonary cases do quite well, contrary to the view often expressed. Care must be taken to avoid overheating and exposure to the sun must be very gradual, with adequate ventilation. The other point is the necessity for keeping the atmosphere over our large towns and manufacturing areas free from the pollution of smoke.

W. M. BAYLISS.

Primitive Culture Analysed.

Early Civilisation: an Introduction to Anthropology. By Alexander A. Goldenweiser. Pp. xiv+428. (London, Calcutta, and Sydney: G. G. Harrap and Co., Ltd., n.d.) 15s. net.

DR. GOLDENWEISER has long been known for his acute criticism, in various journals, of the theories and constructive efforts of the most noted ethnologists; we therefore welcome in this introduction to anthropology an exposition of his matured views, though his book will but partly supply the need there is for a systematic treatise on ethnology.

The book consists of three parts: the first deals with a general sketch of the Eskimo, Tlingit and Haida, Iroquois, Baganda, and Central Australians, as illustrative of distinct civilisations, though in each case one of their respective cultures has been given more careful treatment than the others. Goldenweiser correctly states that "the only way to know early civilisation is to study it in the wholeness of its local manifestation." The various activities and beliefs of a people are so intimately interwoven that quite wrong inferences may be drawn if a custom is separated from its context and compared with an analogous custom isolated from another group. These five accounts afford material for future discussion; as the author states, other groups would have served as well, but these suffice for practical purposes without rendering the book unwieldy.

The second part deals with industry, art, religion and magic, and society, which are considered partly from the point of view of special cases and partly constitute a limited comparative survey. There is a great deal of valuable matter in this section, but there are also many aspects of culture that are not alluded to, possibly from lack of space. For example, the researches of A. R. Brown on various Australian tribes throw new light on Australian sociology, and what is often termed "soul substance" is not mentioned. In discussing diffusion *versus* independent development in early civilisation some valuable reflections are made. Graebner's views are slightly criticised, Elliot Smith is dismissed with scorn, but Rivers is dealt with at greater length, though some of his arguments are described as "highly artificial." The author concludes by saying "we must reiterate our former position that the diffusion of civilisation from tribe to tribe is but one of the basic factors in cultural advance, the other factors being human creativeness, resulting in the independent origination of new things and ideas," though elsewhere he says, "the civilisational rôle of borrowing is fundamental."

In the third part Dr. Goldenweiser discusses various theories of early mentality: those of Herbert Spencer, that the ghost is the corner-stone of early theology, that spirits are derived from ghosts, the nickname theory of animal and other cults; the views of Frazer on magic and its relation to science and religion, the origin of exogamy. He says that "Wundt approached the problem of primitive mentality with a far broader and deeper equipment in scientific method than did Spencer, Tylor, or Frazer. As a student of psychology he was proof against the allurements of a facile mode of interpretation of primitive thought, of which these authors are so often guilty. He discarded the crude rationalism of Spencer and Tylor. . . . The associationism of Frazer also collapsed before Wundt's critical onslaught," but even Wundt often failed "to escape the allurements of monogenetic derivations." Durkheim also receives very favourable consideration, though his "tremendous exaggeration of the import-

ance of social factors as contrasted with all others" is duly noted, and he "fails to do justice to the contribution of the individual to religious experience." He also disagrees with certain aspects of Lévy-Bruhl's views, and with Rivers in his criticisms thereon; he, like others, cannot accept Freud's Cyclopean family or his conception of totemism.

The last chapter on early life and thought is an admirable constructive effort on the part of the author, in which he ranges himself on the side of the French and German psychologists as opposed to British anthropologists.

As Dr. Goldenweiser freely criticises others, he cannot object to having a few of his own shortcomings pointed out. Buganda lies north and north-west of the Victoria Nyanza; we are told that "maize is perhaps the principal staple food" of the Baganda (p. 83), but Roscoe says no grain is grown and that plantains furnish their staple food. There are more varieties of Australian canoes than the two bark ones he refers to, and the dingo is not a wolf, but allied to the Indian dog. The decorative art of Australia is more varied than he imagines, and ceremonies for the multiplication of totemic animals are not confined to the Aranda, as he seems to imply (pp. 109, 281). Pile dwellings and tree houses have a more extended range than is indicated (p. 135). The great stone images of Easter Island are not "wooden idols" (p. 306). It is incorrect to describe Elliot Smith as a "follower" of Rivers; if anything, the reverse is nearer the mark. The statements are erroneous that "Man has never used man as a regular article of diet . . . we do not hear of the eating of relatives" (p. 396). Throughout the book the term "etching" is used for engraving or incising: etching is a definite technical process.

A. C. Haddon.

Sir Alfred Yarrow.

Alfred Yarrow: his Life and Work. Compiled by Eleanor C. Barnes (Lady Yarrow). Pp. xv + 328 + 78 plates. (London: E. Arnold and Co., 1923.) 10*s.* 6*d.* net.

LADY YARROW has given us a most interesting and genial account of the life and work of Sir Alfred Yarrow and has successfully portrayed, in happy and engaging style, a character which Smiles would assuredly have been glad to utilise in his examples of "Self Help," and to have included in his "Lives of the Engineers." She has succeeded in showing not only the shrewd business capacity of Sir Alfred, but also his remarkable ability to apply science to the needs of the great industry with which he was chiefly associated, especially in those branches in which he was in the front rank of pioneers for a very long period. His admiration for the attainments and discoveries of the man of science stands high, but it is equalled by his appreciation of the sound sense and fertility of resource of the skilful manual worker; and a perusal of the book will indicate the reasons for his being in the forefront of those who have derived advantage from the happy combination of the two.

Lady Yarrow shows that Sir Alfred, equipped with an abundance of scientific and general knowledge, was quick to perceive when the teachings of science or of handicraft, or both, could be brought to the aid of his problems, and, soon satisfying himself of the accuracy of his premises (generally by the help of homely but convincing experiment), he rapidly proceeded to successful solution, mostly with satisfactory and frequently with far-reaching results.

It has fallen to the good lot of many to have been associated with Sir Alfred in some portions of his comprehensive work; few, if any, can have been connected with the whole of the developments in shipbuilding and marine engineering in which he has taken such a prominent part, and this story of his life consequently contains much of interest that must be new to every individual reader, however intimate his acquaintance for a period may have been. To all such the book will be highly reminiscent, and naval engineers in particular will recall many exciting incidents of the trying times which marked the endeavour to get better than their best from the coal-fired boiler and the high-speed reciprocating engine, each in its special pandemonic environment. As described in the book, these experiences constituted a phase provoked by the demand for high speeds which necessitated the use of extremely light machinery, and they had to be endured to prepare the way for the engine-room conditions that we now enjoy—perfect peace with oil-fired boilers and turbines.

Sir Alfred Yarrow's part in the development of high-speed craft is generally well known, but the full extent of the part he took during the War is perhaps not so widely known. The chapters devoted to this portion of his work do not disclose the whole of his efforts, so remarkable in one of his advanced years, but they are sufficient to reveal his high sense of patriotic duty, and the versatility and value of his vigorous endeavours. He enjoyed the confidence of Lord Fisher in his work for the Navy, and amply proved that the confidence was justified.

But, in addition to his high professional reputation, Sir Alfred is esteemed for his kindly disposition coupled with more than an ordinary desire to help his fellow-men. The author's note at the end of the volume delineates this side of Sir Alfred's character in touching words,

and her interesting descriptions in the text of his principal philanthropic schemes supply further details. His own ideas of how to dispose of "a balance at the bank in excess of what is necessary" are given in Chapter XX., "The Convalescent Home," and are commended to readers, who will afterwards understand more readily the unique reasons for Sir Alfred's many generous benefactions during his lifetime.

Lady Yarrow has evidently compiled her work under some restraint, as more could be told both of Sir Alfred's professional success, and of his bounty, and his methods of encouraging others (for example, his recent munificent gift to the Royal Society is not mentioned in this book), but she has told enough to warrant Sir Alfred's claim that "his business life has been filled with sentiment and friendship." She is to be congratulated on the scheme, sequence, and style of the compilation, and she can be assured that her work will be highly appreciated by the very large circle of Sir Alfred's friends.

G. G. Goodwin.

Our Bookshelf.

Grundriss der allgemeinen Zoologie für Studierende. Von Dr. Alfred Kühn. Pp. viii + 212. (Leipzig: Georg Thieme, 1922.)

This is a wholly admirable text-book. We know of no book in the English language exactly like it, none that attempts so much within so limited a space, and, moreover, attempts it so successfully, with a due regard to the requirements of those for whom it is written and to the maintenance of a proper balance between the various parts of the subject. The book is divided into three approximately equal parts, the first giving a rapid survey of the morphology of each phylum of the animal kingdom, the second an account of the physiology of animals, and the third a review of the main principles of embryology and the problems of variation, heredity, sex, and evolution. The book concludes with a short bibliography of more advanced text-books and original memoirs to which the student can turn for more detailed information on any point.

In attempting to treat of the whole of the animal kingdom in 70 pages, the author may be thought to have essayed an impossible task. By confining himself to the broad and general characters of each phylum, without entering into details of any one type, however, and aided by an excellent series of diagrammatic figures, he has succeeded in giving an admirably clear account of each phylum. The book is intended for medical students, and, consequently, special emphasis is laid on parasitic forms throughout, without, however, overburdening the book in this way or losing the general perspective of the whole. The illustrations have been mainly drawn specially for this book. They are, in the majority of cases, schematic drawings, very clearly reproduced and excellently chosen for the purpose, and would make good wall diagrams for lecture purposes.

The point which most impresses us in this book is the excellent balance which the author has kept between the three broad divisions of zoology—morphology, physiology, and embryology—with its kindred problems. The general course given to first-year medical students is apt to be weighted too much on the morphological side; physiology is generally neglected, and very little consideration is given to the fundamental and general problems of zoology. We feel sure that a course on the lines so admirably sketched by Prof. Kühn would give the medical student a broader outlook on zoological subjects, would interest him more for its own sake, and would make abundantly clear to him the fundamental bearing of his zoology course on his future life's work. He would no longer regard zoology as a subject put into his curriculum for his ultimate confusion, to be got through with the minimum amount of work in the minimum time. With a little amplification, Dr. Kühn's book would serve as a basis for subsidiary one-year courses in zoology for science students.

Our Solar System and the Stellar Universe: Ten Popular Lectures. By the Rev. Charles Whyte. Pp. xi + 234 + 18 plates. (London: C. Griffin and Co., Ltd., 1923.) 10*s*. 6*d*. net.

The ten lectures which form the basis of this volume were delivered as the Thomson Lectures for the session 1919–1920 in connexion with the United Free Church College, Aberdeen. They provide a survey—fairly up-to-date and in general accurate—of the present state of astronomical knowledge, in a form suitable for the non-scientific reader, so far as it is possible to do so without the introduction of mathematics or of mathematical reasoning.

There are a few errors to which attention may be directed. The statement on p. 27 that "the theory now generally accepted as being the chief cause in the maintenance of the sun's heat, is that advanced by Helmholtz in 1853," is not correct. It is well known that this theory is not in accord with geological facts. Again, on p. 60, it is stated that a temperature of 750° F. at the surface of a planet corresponds to an intensity of the rays of the midsummer sun multiplied by 9. This is, of course, a fallacy. The rotation period of Mercury is not known with certainty, though from p. 61 the contrary would be inferred. It is certainly exceeding the limits of scientific truth to say, as on p. 151, that "we have every reason to believe that a number of planetary bodies, many of them exceeding in size our own solar satellites, travel round these suns in swift motion over enormous circumferences," while on p. 164 the sentence, "They (the Cepheids) are situated from us at enormously greater distances than those which up to now have been measured," requires modification. In dealing with the Martian canals, their possible subjective nature might have been mentioned. The detailed elementary calculations on pp. 61-2, 87-8 might have been omitted with advantage.

The book is well produced, with good paper and clear type. The plates have been carefully selected, and it is a pleasure to see them reproduced on well-glazed paper. Too frequently astronomical photographs lose much of their value when reproduced in popular works, through the use of inferior paper. The book can be recommended as one which will provide much interesting reading to those who, though without scientific training, are interested in astronomy.

H. S. J.

Some Questions of Phonetic Theory. By Wilfrid Perrett. Chapter 6: The Mechanism of the Cochlea. Pp. 39-80. (Cambridge: W. Heffer and Sons, Ltd., 1923.) 2*s.* net.

THIS section of Mr. Perrett's book is an attack on the resonance theory of hearing, and on all those who have written in support of it. It is his avowed object "to lay the yammering ghost of 'sympathetic resonance' in the cochlea" (p. 44). His criticisms of the resonance theory are under three headings: (1) An attack upon Helmholtz's theory of beats as he conceives it. The construction he puts upon Chapter VIII. of the "Tonempfindungen" is, in the reviewer's opinion, forced and unfair. (2) An uncorroborated personal experience of his own which leads him to the conclusion that the ear can distinguish two notes "in perfect physical unison" sounded simultaneously. (3) That speech sounds can terminate suddenly in a "voiceless-occlusion" consonant, consequently no "after vibrations" of the basilar fibres occur. Mr. Perrett quotes graphic speech records, but admits that the evidence drawn from them is inconclusive.

We gather that Mr. Perrett has abandoned the Wrightson theory in favour of a "travelling-bulge" theory on the lines of those of Meyer and ter Kuile, but he does not appear to have brought forward any additional evidence in support of this view. He tells us that the preceding four chapters of his book have been received "with gratuitous contumely in certain quarters" (p. 59). We cannot help thinking that his manner of conducting a controversy may have been responsible to a certain extent for the treatment his work has received. G. W.

The Americas. By J. Bruce. (The "Explorer" Geographies). Pp. viii+216. (London: G. Bell and Sons, Ltd., 1922.) 3*s.*

A NEW note is introduced into elementary geographical teaching by this volume, which appears to be the first of a series. After an introductory chapter on map-reading, there are several chapters describing the way in which the American continent was discovered and opened up by Europeans. The sections are vividly written and cannot fail to interest, although the paragraphs and map dealing with Arctic Canada and the North-west passage would bear some revision. Then follows a general geographical survey of the Americas. Eight double-page plates with full descriptions are a notable feature, and there are in addition several sketch maps and two coloured orographical maps. The list of books for students' reading is useful, but might well be extended. The book as a whole gives a far more vivid picture of North and South America than the more formal analytical text-books succeed in doing. R. N. R. B.

Elements of Glass-blowing. By Dr. H. P. Waran. Pp. ix+116. (London: G. Bell and Sons, Ltd., 1923.) 2*s.* 4*d.* net.

DR. WARAN's book deals in a clear and practical way with many things which a research student will find that he requires to know. The ability to put together and to repair simple glass apparatus is one of the things which he should gradually acquire, and this book will be found a useful guide in this direction. It is very doubtful whether the laboratory worker will find it desirable to make his own stopcocks or Dewar vessels; the time spent on such work would usually be more profitably applied in research, but in places where apparatus is not easily obtained it may be quicker to make it. As a general rule, unless one has become very proficient in glass-working, it is usually cheaper and quicker to leave complicated things to the professional man.

The Wonders of the Stars. By Joseph McCabe. Pp. ix+114+4 plates. (London: Watts and Co., 1923.) 3*s.* net.

THE author has written a series of volumes on various phases of evolution; the present book belongs to the series, and discusses the light that has been thrown on stellar and planetary evolution by the discoveries of the last half-century. As an illustration of the difficulty of keeping up-to-date in discussing the status of the spiral nebulæ, some of the views of leading astronomers in favour of the "island-universe" theory that are quoted in the book have already been modified by the discovery of their rapid rotation.

While a few sentences here and there might be picked out for criticism, chiefly the statement of matters of conjecture as facts, on the whole the picture given of our present knowledge of the universe appears to be correct, and as complete as can be expected in the space of 112 pages. We sympathise with the author's appeal for a general agreement among astronomers as to the meaning of a "billion." A. C. D. C.

Astronomie: Grösse, Bewegung und Entfernung der Himmelskörper. Von A. F. Mobius. 13 Auflage, bearbeitet von Prof. Dr. Hermann Kobold. Teil 2: Kometen, Meteore und das Sternsystem. (Sammlung Göschen Nr. 529.) Pp. 128. (Berlin und Leipzig: W. de Gruyter und Co., 1923.) 1*s.*

THIS little book has three chapters dealing with comets and meteors, the fixed stars, and cosmogony respectively. This restriction of subjects enables each to be treated pretty fully, in spite of the small size of the volume. The information is brought up-to-date, and includes recent comets, the Giant and Dwarf theory, and a discussion of the planetesimal theory. The star-maps give the positions of all stars of magnitude 5 or brighter down to south Decl. 45°. A. C. D. C.

Tracks of British Animals. Edited by H. Mortimer Batten. (Edinburgh: W. and A. K. Johnston, 1923.) 4*s.* net.

THIS publication takes the form of a chart, 20 in. × 30 in., depicting in life-size the spoors of the commoner British wild animals and of domestic animals for comparison, with brief explanatory notes by the editor. The diagrams are boldly and clearly printed and the chart should be of the greatest use for the teaching of nature study in schools and for the instruction of Boy Scouts and Girl Guides in the craft of the country-side. The omission of a figure of the track of a dog is one that should be made good in a future edition.

Letters to the Editor.

The Editor does not hold himself responsible for opinions expressed by his correspondents. Neither can he undertake to return, nor to correspond with the writers of, rejected manuscripts intended for this or any other part of NATURE. *No notice is taken of anonymous communications.*]

Photographic Plates for the Extreme Ultra-Violet.

IN recent years there have been a number of attempts to improve the photographic methods, perfected by Schumann, used in the investigation of the ultra-violet, so far without any very striking results.

Recently Mr. David Mann and I have been making some experiments with the daguerreotype process. The results, though interesting, are so far of no great practical value. It is not difficult to prepare a surface which will be very sensitive in the region about wave-length 1850 Å.U., and on two or three occasions we have obtained records extending to wave-length 584 Å.U., but in general the behaviour of the plates in the extreme ultra-violet is capricious and unsatisfactory.

Duclaux and Jeantet (*Journal de Physique*, ii., 1921, p. 154) have described a way of "Schumannising" an ordinary dry plate by treating it with sulphuric acid, and recently Aston has referred to the same process. M. Duclaux has been so kind as to send me some specimens of the results he has obtained. He informs me, however, that he prefers another method which he and his colleague have discovered, described in their article just cited. His experiments were confined to the region of the spectrum which may be investigated with a quartz prism spectrograph; I have continued them into the extreme ultra-violet.

The procedure is extremely simple. A fast commercial photographic plate (I have employed a "Seed 30") is coated with a thin film of a colourless paraffin oil. It is then exposed in the usual way in a vacuum spectroscope, the oil is removed with acetone and the plate is developed. The results are nearly, though not quite, as good as those which I have obtained with the most sensitive Schumann plates prepared according to the old method; it is quite easy to get a record of the strong helium line at λ584 Å.U.

The success of the process evidently depends on fluorescent action; I have tried a number of different kinds of oil, and I find that "Nujol," a very pure oil sold in this country for medical purposes, yields good results.

I feel sure that this discovery of Duclaux and Jeantet will prove a real blessing to all spectroscopists who work in the extreme ultra-violet.

THEODORE LYMAN.

Jefferson Laboratory, Harvard University,
June 28.

The Presence of Urease in the Nodules on the Roots of Leguminous Plants.

AFTER the discovery of urease in the Soya bean by Takeuchi in 1909, the presence of this remarkable urea-splitting enzyme was soon recognised in the seeds of many leguminous plants. On the other hand, while the occurrence of the enzyme in seeds from widely different varieties of plants has been recorded in recent years, its absence from the seeds of several Leguminosæ has also been noted.

So far as we have been able to ascertain, the peculiar root nodules of leguminous plants have not hitherto been tested for urease. Experiments carried out in this laboratory in conjunction with Mr. J. V. Collins have revealed the presence of the particular enzyme in all the cases examined. Crushed nodules taken from the well-washed rootlets of *Trifolium procumbens*, *T. pratense*, *T. repens*, *Vicia sativa*, *Medicago sativa*, *Galega officinalis*, various lupins, and the garden pea, were placed separately in a two per cent. solution of urea (sterilised by saturation with toluene) to which a few drops of neutral phenol-red solution had been added as indicator. A purple-red colour, due to ammonia generated from the decomposition of urea, was gradually developed in the solutions, after they had been maintained at 55° for about an hour. Several control experiments showed that ammonia was not generated in the absence of urea, and that the solution of the latter alone did not change the colour of the indicator under the above conditions. Also, rootlets not bearing nodules, and roots taken from plants belonging to several different natural orders, failed to give any evidence of the presence of urease. Judging from qualitative experiments, nodules from the white and the yellow tree lupin appeared to be the most active of those examined.

From these observations it must be concluded that the nodules on the roots of leguminous plants possess an additional function to the one which they have been known to perform since Hellriegel's discovery. While we have not found urease in any roots devoid of nodules, clear evidence was obtained of its presence in the cylindrical tuberous growths developed from the rootstock of the lesser celandine (*Ranunculus Ficaria*). This is the only case so far in which the enzyme has been detected in the adjunct of a root outside the leguminous family of plants.

An interesting demonstration of the presence of the enzyme can be made without crushing the nodules. The entire root cut from a young pea plant, or preferably from a young lupin, as it usually carries larger nodules, is immersed in a solution of urea containing a liberal supply of the indicator (neutral phenol-red). The action of the enzyme is allowed to continue until the solution has attained a rich purple-red colour, which of course requires a much longer time than if the nodules had been crushed. The root is now removed from the solution, rinsed for a few moments under the tap and then placed in water to which a few drops of the indicator have been added. The diffusion of alkaline solution from nodules into the outer liquid can be readily observed by the zone of colour which forms in the solution directly round the nodules.

While the first part of this experiment illustrates the relatively feeble activity of the nodules *in situ*, if the root be now washed in running water until the colour of the indicator is no longer affected, it will be found that when immersed again in a solution of urea the rate at which the latter is decomposed will be much greater than when the nodules were tested originally. This obviously suggests that urease is produced within the nodules during contact with the urea solution. Under natural conditions the micro-organisms present in the nodules are probably concerned in the generation of the enzyme as required. In our experiments the antiseptic power of toluene was apparently insufficient seriously to affect their activity. Pending a more extended investigation of the subject, our preliminary observations seem worth recording.

Trinity College, Dublin.

Solar Activity and Atmospheric Electricity.

DR. CHREE in a recent paper,[1] giving the results of his investigation based on the Kew atmospheric-electric data, reaches the following interesting conclusion, as stated in his abstract: "The results obtained are on the whole not incompatible with Dr. Bauer's conclusion, but they indicate that if a relationship of the kind supposed exists, the sun-spot influence must be very much less in the case of atmospheric electricity than in that of terrestrial magnetism." The conclusion[2] referred to by Dr. Chree is that the potential gradient of atmospheric electricity apparently varies during the sun-spot cycle, increasing with increased sun-spot activity, and that the diurnal range of the potential gradient of atmospheric electricity, like the diurnal range of terrestrial magnetism, increases with increased sun-spot activity.

I fully agree with Dr. Chree that if there is a relationship between solar activity and atmospheric electricity, it ought to turn out to be a world-wide phenomenon, just as in the case of the recognised relationship between solar activity and terrestrial magnetism. However, this fact is to be kept in mind, that disturbances, because of local conditions, play a far more predominant rôle in atmospheric electricity than in terrestrial magnetism, and may in fact be of such a character as to mask completely any world-wide effect. Accordingly, in atmospheric electricity a very careful selection of stations is necessary for the study of world phenomena. It thus may turn out that one very favourably located station, such as the Ebro Observatory at Tortosa, Spain, upon the excellent and consistent observations of which my first conclusions were chiefly based, may lead to a more certain result than a dozen unfavourably located stations.

One of the best criteria for judging the unfavourableness of a station is the ratio c_2/c_1 of the amplitude of the 12-hour and 24-hour waves, respectively, of the potential gradient; the smaller the ratio the more readily does the station show "universal" or "terrestrial" results. This ratio at Kew is one of the largest of any of the stations known to me; it varies between winter and summer from about 1 to 5, and on the average for the year is 2 against 0·8 for Ebro, 0·7 for Eskdalemuir, and 0·25 for the oceans. Furthermore, the absolute value of the potential gradient at Kew is more than twice the average normal value for the region of the earth from 60° N. lat. to 60° S. lat. However, in spite of the disturbed character of the Kew station, Dr. Chree has succeeded in getting results which he says are not incompatible with mine, and I shall show how, by the recognition of another variation to which atmospheric electricity appears to be subject, the validity of his results respecting the sun-spot effect may be enhanced.

Every series of carefully made and undisturbed observations, extending over a period approximating a sun-cycle or more, has received investigation and definite results have, in general, been obtained. A notable exception is Potsdam, where, because of severe climatic disturbances, instrumental changes, and changes in reduction factor, the extensive series of observations at this station unfortunately is subject to discontinuities and therefore cannot safely be utilised for the detection of a sun-spot effect. For the present sun-spot activity, as indicated by the Wolf or Wolfer sun-spot number, is taken as a measure of solar activity, the possible influence of which upon atmospheric electricity is to be investigated. Other measures of solar activity—for example, prominences—are likewise included in the complete investigation.

Suppose we have for a series of years the mean annual values of the potential gradient P in volts per metre, as resulting from continuous registrations throughout the year and based only on electrically undisturbed days, without negative potential. Let P_m be the mean value of P for the entire series corresponding to the mean date T_m, and let S_m be the mean annual sun-spot number; then with fair approximation a formula of the following type is found to hold:

$$P = P_m + s(S - S_m) + t(T - T_m). \quad . \quad . \quad (1)$$

The coefficient s represents the change in P corresponding to one sun-spot number, and t represents the time-effect or annual change in P dependent, apparently, upon the average character of the particular sun-spot cycle in which the series of P-observations happens to occur.

For nearly every series discussed thus far, when the station is fairly free from pronounced local or climatic disturbances and the annual values of P have been derived from electrically-undisturbed days, the coefficient s is found to be positive and averages about 0·30 per cent. of P_m for the mean of the year; hence, if the sun-spot development from minimum to maximum is 100 numbers, *the potential gradient* P *suffers an increase from the year of minimum sun-spot activity to the year of maximum sun-spot activity of about* 30 *per cent. of* P_m. (See Table 1.)

The value and sign of the coefficient t may depend upon whether the sun-spot cycle in which the P-series occurs is below or above average development. Thus the present cycle, beginning with the year 1913 of minimum sun-spot activity, is above average development; hence t turns out to be negative, as shown in Table 1. No such high mean annual sun-spot number as 103·9 for 1917 has occurred since 1870, when S was 139·1. How t may vary with cycle, and s with season of year, will be discussed in the complete paper which is to appear in the September 1923 issue of *Terrestrial Magnetism and Atmospheric Electricity*.

The values of s and t, expressed both in percentages of P_m and in volts per metre, as determined by the method of least squares, will be found given in Table 1 for three observatories, from Spain to Scotland, and the mean epoch 1916. The third and second columns from the end of Table 1 contain the mean square errors, μ_o and μ_c, obtained respectively, first on the assumption that the departures of P from the mean value P_m represent errors of observation, and secondly that formula (1) applies. It will be seen, from a comparison of the figures in the two columns, that by the application of the corrections (sun-spot effect and cycle or time effect) a very much better representation of the observed values of P is obtained than by the arithmetical mean P_m.

The last column, r_s, contains the correlation coefficient between potential gradient and sun-spot activity after the application of the corrective term $-t(T - T_m)$ to the observed values of P. It will be observed that, in general, the coefficient so nearly approaches unity, especially for Ebro and Eskdalemuir, as to leave scarcely any doubt of a definite relationship between the potential gradient of atmospheric electricity and sun-spottedness. By the recognition of the t-change, which is similar in its effect to the secular change in terrestrial magnetism,

[1] "A Supposed Relationship between Sun-spot Frequency and the Potential Gradient of Atmospheric Electricity," Proc. Phys. Soc., London, vol. 35, Part 3, April 15, 1923, pp. 129-136.
[2] *Terr. Mag. and Atm. Elec.*, vol. 27 (1922), p. 30; see conclusion *f*.

except that it is of shorter period and seems to vary from cycle to cycle, Dr. Chree's correlation coefficient for the Kew series 1911 to 1921 is increased from 0·55 to 0·77, and for the less regular series 1898 to 1909 from 0·24 to 0·62.

TABLE 1.—RELATION BETWEEN ANNUAL POTENTIAL GRADIENT OF ATMOSPHERIC ELECTRICITY AND ANNUAL SUN-SPOT ACTIVITY.

Observatory.	Period.	Weight.	T_m.	S_m.	P_m.	s.	t.	s.	t.	μ_o.	μ_c.	r_s.
					Volts per m.	Volts per m.	Volts per m.	Per cent of P_m.	Per cent. of P_m.	Volts per m.	Volts per m.

11	1921·1	24·7	86	−27	−21·0	92	−6	−23·6	− 4·6	−13·6	−18·6	−5·0

Let us take, for example, the change in the observed values of the potential gradient P_o between 1917 (year of maximum sun-spot activity) and 1921, as shown in Table 2. The observed change (decrease) at Ebro amounted to 39 per cent.; the computed decrease, according to formula (2), is 36 per cent.; 25 per cent. being contributed by the sun-spot term and 11 per cent. by the cycle or ΔT-term (see columns 9, 10, 11, and 12). That this remarkable decrease at Ebro between 1917 and 1921 was a world-wide phenomenon, besides being corroborated by Eskdalemuir and Kew, is further shown by the fact that the results of the *Carnegie* potential-gradient observations on the oceans, all instrumental and reduction constants having been most carefully controlled throughout the various cruises of the *Carnegie*, gave a mean value for 1921·5 which was about 30 per cent. less than the corresponding value for 1917·5.

There are no such correspondingly large changes in terrestrial magnetism during a sun-spot cycle as have just been shown to occur in atmospheric electricity. According to my 1918 investigations [3] an increase of 100 in the sun-spot number would correspond to a decrease in the intensity of magnetisation of the earth of about 0·1 per cent., whereas for an increase of 100 in the sun-spot number the normal potential gradient of atmospheric electricity was increased about 30 per cent.

The investigations thus far would indicate that the *electric conductivity* λ does not vary with sun-spot activity in the same marked degree as does the potential gradient P; hence, as the current density of the vertical current is $i = \lambda P$, we may say, with high degree of certainty, that the vertical conduction current increases with increased sun-spot activity at the rate of about 3 per cent. per 10 sun-spot numbers. The bearing of this most interesting fact upon theories of the origin and maintenance of the earth's negative electric charge needs no elaboration here.

But of equal importance with the sun-spot effect to theories is the cycle effect, which indicates that the earth's negative charge, even if all periodic variations and sun-spot effects are eliminated, is not maintained constant but may progressively, from year to year, show in one cycle a steady diminution, and in another a steady increase. During the present cycle, beginning with the year of minimum spottedness, 1913, the total decrease may be such that the potential gradient at Ebro in the approaching year of minimum, 1923 or 1924, may be about 30 per cent. less than in the minimum year of 1913, when the observed value was 110 volts per metre. But, as already intimated, the cycle effect may not always be a diminishing one. I hope to study the variations in t more exhaustively by utilising all past data obtained with the requisite care.

Lack of space will not permit describing here in detail the various examinations already made concerning the *effect of sun-spot activity on the periodic variations of the potential gradient of atmospheric electricity*. Dr. Chree in his paper cites the results drawn by me from a Fourier analysis of the diurnal variation of P at Ebro for the period 1910 to 1920, and he finds a correlation coefficient of 0·72; if account be taken of the cycle effect, which is also evident here, as the diurnal variation is a function of the absolute value of P, then the correlation coefficient is 0·96. The analysis has been extended so as to include the data for 1921, which have become available since the 1922 paper.

In my 1921 investigations, which Dr. Chree apparently overlooked, I investigated the relationship between the *range* of the diurnal variation of the potential gradient at Ebro and sun-spot activity, and found that the sun-spot variation in the diurnal range between minimum and maximum was about 25 per cent., and that it increased with increased sun-spot activity.[4] With the aid of a similar formula to (1), and taking the Ebro series 1911–1921, the value of s turns out to be +0·31 for the mean of the year; *i.e.* an increase in the sun-spot number of 100 between minimum and maximum, which was about the case for the present cycle, was accompanied by an increase of 31 per cent. in the diurnal range at Ebro. A similar result is found for the Kremsmünster series, 1903–1910. The average corre-

[3] *Terr. Mag. and Atm. Elect.*, vol. 23 (1918), p. 63.

[4] *Terr. Mag. and Atm. Elec.*, vol. 26 (1921), p. 68, conclusion *b*, and Fig. VII., fifth curve.

lation coefficient for the sun-spot effect on the diurnal-variation (range, average departure, Fourier combined amplitude) of the potential gradient for various stations is about 0·8; for Ebro and Eskdalemuir it exceeds 0·9. The reason that Dr. Chree gets somewhat unsatisfactory results from certain diurnal data at Kew is partly because of the fact, already mentioned, that Kew is not a favourable station for the most successful study of world effects. However, applying a formula similar to (1) to the Kew series 1898–1909, Dr. Chree's correlation coefficient for the sun-spot relation of his quantity c_r (combined amplitude of the 24-hour and 12-hour waves of the Fourier series) is increased from 0·46 to 0·77; $s = +0{\cdot}50$ per cent., and $t = -2{\cdot}11$ per cent. of c_r.

The *sun-spot influence is also shown in the annual variation of the potential gradient at Ebro*, for the period 1910–1921; the correlation coefficient is 0·71.

General Conclusion.—The relationship between sun-spot activity and atmospheric electricity turns out to be, for locally undisturbed stations, as definite as in the case of terrestrial magnetism; the sun-spot influence on the periodic variations of the atmospheric potential-gradient is, in general, as great as on the periodic variations of terrestrial magnetism; and as concerns the effects on the absolute values, the sun-spot influence is about 300 times greater in atmospheric electricity than in terrestrial magnetism. The potential gradient of atmospheric electricity, and, presumably, the earth's total negative electric charge, is furthermore subject to an annual or secular change, which may vary in magnitude and sign from one sun-spot cycle to another.

Use of Yeast Extracts in Diabetes.

IN a previous letter to NATURE of March 10 (111, p. 327) we stated that we had obtained from yeast an insulin-like substance which had the effect of lowering the blood sugar of normal animals. Later we described the beneficial effect of this extract on some cases of diabetes mellitus (*Brit. Med. Journ.* i. p. 711, 1923). We soon found that the activity of the extract from different samples of yeast varied very widely. The results of these experiments will be published at a later date in conjunction with Dr. H. B. Hutchinson. In this connexion it is of interest to note that Collip (Proc. Soc. of Exp. Biol. and Med., 20, p. 321, 1923) reports numerous failures before he succeeded in obtaining an active extract from yeast, and later Funk and Corbitt (Proc. Soc. of Exp. Biol. and Med., 20, p. 422, 1923) have met with similar variability.

We have recently obtained from the action of micro-organisms other than yeast extracts which have a very considerable power of lowering the blood sugar of normal animals to a point where convulsions occur. That the convulsions were not due to a toxic effect is shown by the fact that they were relieved by injection of glucose. The extract like that from yeast caused the blood sugar to be lowered for a much longer time than when insulin was used. Whether these extracts will be of practical importance remains to be decided. Experiments are being directed to this end.

Tenacity of Life of an Eel.

I HAVE lately had occasion to notice a further proof of the tenacity of life exhibited by the eel, which may perhaps be of interest.

A correspondent in America, Mr. L. L. Mowbray, of the Aquarium, Battery Park, New York City, has kindly sent me from time to time specimens of elvers[1] of the American eel, preserved in formol, for investigation purposes. Quite recently, a parcel from Mr. Mowbray was delivered at the laboratory here. Greatly to our surprise, however, instead of elvers preserved in formol as usual, it proved to contain a single specimen very much alive.

The little eel was enclosed in a small glass bottle (quarter-litre size), which had been corked and waxed so as to render it perfectly air-tight, and the bottle again enclosed in one of the tin cylinders commonly used in the United States for sending natural history specimens by post. The tiny creature had thus made its voyage across the Atlantic in complete darkness, and without any renewal of air in the 200 c.c. of water in which it was originally placed.

The postmarks showed that it had left New York on April 19, and arrived in Copenhagen on May 19, 1923. It has now been transferred to a small aquarium, where it is still alive and active, to all appearances in excellent form after its lengthy journey.

Evidently, then, the American fresh-water eel is by no means inferior to its European cousin in respect of endurance and tenacity of life.

I may add that we have, at the Laboratory here, two live adult specimens of the American eel. They have been in our aquaria since 1914, when we brought them home, as elvers, from Santa Cruz, in the West Indies. They, however, made the journey in an open beer bottle, with frequent changes of water, and were thus not subjected to so severe a test of endurance as the specimen above mentioned.

[1] The youngest stages of eel-fry which make their way up into fresh water are called elvers.

Adsorption on Soil-Grains.

THE recently published work by Messrs. J. Hendrick and G. Newlands (*Journ. Agric. Sci.*, January 1923) on the mineral particles in the coarser grades of the "fine earth" separated from soils was noticed in NATURE of June 9, p. 736, and it was remarked that "the study of adsorptive reactions should not be entirely restricted to the colloidal field."

It is of interest to note that the United States Department of Agriculture took up this question last year, and its Bulletin No. 1122 (October 21, 1922) records the work of Messrs. M. S. Anderson, W. H. Fry, P. L. Gile, H. E. Middleton, and W. O. Robinson, on "Absorption by colloidal and non-colloidal soil constituents." The authors worked on material finer than 2 mm. in diameter, which, in common with so many experimenters, they call "the soil," by an unfortunate restriction of the term. This earth is separated, preferably by centrifugal methods, into three grades, 2·000–0·050 mm., 0·050–0·001 mm., and less than 0·001 mm., the last being styled colloidal. In testing the relative powers of adsorption on (or absorption by) these grades, it was justly felt that samples really free from colloidal matter could be best obtained by crushing unaltered minerals. In

each case, the grade 0·050–0·001 mm. was selected and examined under the microscope, the particles being counted and measured; the surface exposed by samples weighing one gram was thus determined for a number of common minerals.

The conditions of comminution seem, however, not quite comparable with those in natural soil-material, where it may be doubted if quartz and garnet, for example, present so large a surface in comparison with other minerals as appears from the table on p. 9. Limonite, again, is probably distributed in soils in a much finer form than is suggested by the artificially crushed material. Where a mineral grain, again, goes to pieces mainly under chemical action, as in the case of olivine set free from basalt, it may yield surviving cores that are of considerable coarseness. The table referred to, however, has obviously very great interest in connexion with the work of Hendrick and Newlands on the mineral constitution of various grades in a fine earth.

The American absorption-tests have been made with a dye (malachite green), water vapour, and ammonia, according to methods that are carefully stated. Four typical samples from the U.S. soil-series were then treated, and it was found that the absorption by the "non-colloidal minerals" (I should prefer to write "non-colloidal mineral particles") is less than 2 per cent. of the total absorption by the fine earths used. It is pointed out that this result is affected to some extent by the wide range of absorptive power shown by the tests on separate minerals. Reference is made to W. O. Robinson's work on "The inorganic composition of some important American soils" (U.S. Depart. Agric. Bulletin 122, 1914), in which the average constitution of the "silt" group in 26 soils was determined as quartz 51, potash felspars 7, muscovite 7, and other minerals 35 per cent. The dye-absorption is practically nothing for quartz and orthoclase; but the authors of Bulletin 1122 state that in a soil rich in muscovite the absorption by non-colloidal particles may be as high as 7 to 20 per cent. of the total absorption of the fine earth.

The conclusion is that the particles styled colloidal possess absorptive characters that are dependent on their composition and not merely on their fineness of comminution. The authors confirmed this opinion by grinding six selected minerals dry in a steel ball mill to a fineness of 1 micron and less, so as to reduce them to the "colloidal" grade. The coarser particles were then (p. 14) removed by sedimentation extending over several days. The average value for absorption of ammonia by these finely powdered minerals is only 22 per cent. of that given by the "ultra clays" from a number of different soils. The fine quartz and microcline showed practically no absorption for malachite green; but chlorite and muscovite gave results equal to the lowest of those obtained from the colloidal particles in the 33 soils tested. It is pointed out that some alteration may have taken place in the powdered minerals by hydrolysis during the process of separation. Their absorptive power may have been thus increased, and may be in part due to the formation of gels upon the particles. Experiments were then made with synthetic gels, and it now seems highly probable that by far the greater part of absorption in the fine earth of soils is due to gels in the material finer than 1 micron in diameter. The term "colloidal" thus comes to have a more definite significance when applied to the constituents of a soil.

Discovery of Ascodipteron in Ceylon.

HITHERTO the species of this peculiar genus of Streblidae have been known only from the Malayan sub-region. Thanks to the interest taken on my behalf by Mr. W. W. A. Phillips of St. George Estate, Matugama, well known locally as an authority on the Chiroptera, I have to announce the discovery of an encysted female of the genus in the small leaf-nosed bat of Ceylon, *Hipposideros atratus*. The specimen was attached to the skin in the vicinity of the tail, whereas previously discovered specimens have been found either in the wing membrane (Adensamer) or at the base of the ear (Muir). The host, also, is of a species in which these parasites have not been hitherto recorded, and Mr. Phillips informs me that it is usually very free from all such, a character which it shares with the rest of its family.

The identity of the specimen has been confirmed by Mrs. Q. Cattell Kessell, working with Dr. Scott at Cambridge.

RONALD SENIOR-WHITE.

The Kepitigalla Rubber Estates, Ltd.,
Suduganga Estate, Matale,
Ceylon, June 1.

ASCODIPTERON is one of the most remarkable examples of specialisation to a parasitic existence known among insects. It was described by Adensamer in 1896 from a single example found imbedded in the dorsal wing-membrane of a bat (*Phyllorhina* sp.) from the Dutch East Indies. Subsequently Mr. Frederick Muir found a number of examples of another species, imbedded in the skin at the base of the ear, on seventeen specimens of *Miniopterus schreibersi* taken at Amboina; from these he obtained puparia and bred both sexes of the fly, publishing an account of the life-history (1912) and referring the insect to the family Streblidæ.

The newly emerged males and females have fully developed wings and legs. At a later stage the female bores its way into the skin of the bat by the aid of a series of remarkable cutting blades on its proboscis, loses its wings and legs almost entirely (only the stumps being present in the fully imbedded individual), and becomes almost completely encysted under the skin of the host, only the posterior extremity of the abdomen remaining external. The front part of the abdomen becomes enlarged and completely engulfs the head and thorax, which come to lie, as though invaginated, at the bottom of a pit. The imbedded female gives birth to a full-fed larva, which falls to the ground and immediately pupates, as is normal in "pupiparous" Diptera.

The discovery of specimens, which may possibly represent a new species of the genus, in Ceylon is highly interesting.

Antarctic Geophysics.

HAVING been responsible for the final values of g derived from the pendulum observations made in the Antarctic in 1902–3 by Commander Bernacchi and his associate Engineer-Commander Skelton, I wish to direct attention to a point which has apparently escaped your reviewer when making the following statements (NATURE, vol. 111, p. 898): "The mean value of g from the three pendulums used in

1912 [by Capt. C. S. Wright] at Cape Evans was 983·003 from the July series and 983·004 from the August series. . . . Commander Bernacchi . . . obtained the values 982·970, 982·979, and 983·025. . . . These values may be compared with the standard value 981·292 at Potsdam. . . ."

This suggests the existence of a substantial difference between the results of the two British expeditions. This does not, however, seem to be the case. The final value for *g* derived from Commander Bernacchi's observations (National Antarctic Expedition 1901–1904, "Physical Observations," Table V., p. 34) was 982·985. In obtaining this, for reasons stated in the discussion, half weight only was allowed to the third pendulum. Thus the *apparent* difference between the results from the two expeditions is $0{\cdot}018_5$ cm./sec.^{2}. But this is accounted for by the fact that while Capt. Wright accepted for *g* at Potsdam—on which all the Antarctic results really depend—the value 981·292 quoted by your reviewer, I accepted 981·274 on the authority of Sir Gerald Lenox-Conyngham (Roy. Soc. Proc. A, vol. 78, p. 245). The difference between these two assumed values is 0·018 cm./sec.^{2}. Thus the values obtained by the two Antarctic expeditions—not exactly at the same place—really agreed to six significant figures. Though not assigning the importance that Paley did to "undesigned coincidences," I think this coincidence is remarkable enough to be worth mentioning. It would be of interest in this connexion to know what value the German experts assign now to *g* at Potsdam. C. CHREE.

June 30.

The Translocation of Carbohydrates in the Sugar Maple.

THE conclusion of Prof. H. H. Dixon (NATURE, February 23, 1922, p. 236, and October 21, 1922, p. 547) that the translocation of organic substances could take place through the vessels of the xylem appears to have created a mild sensation among plant physiologists. Attention, however, does not seem to have been directed to the behaviour of the sugar maple, which furnishes important evidence in this connexion.

The sugar maple or rock maple (*Acer saccharum*, Marsh) is well known in Eastern Canada and New England as the source of the maple syrup and maple sugar of commerce. To obtain the sap, a small hole about half an inch in diameter is bored into the sapwood to a depth of about 3 inches, at a height of about 4 feet above the ground-level at the time when the snow is melting at the beginning of spring. A metal tube is inserted into the hole, and a small bucket is attached into which the sap drops from the metal spout. The sap as it oozes from the tree is colourless, but becomes brown on concentration by boiling.

A bulletin entitled "The Maple Sap Flow," by Jones, Edson, and Morse, published by the Vermont Agricultural Experiment Station in 1903, gives a full account of observations and experiments on this subject. Some of the conclusions reached by these investigators are as follows: The sap contains about 3 per cent. of sucrose and also small amounts of proteids, mineral matter, and acids, mainly malic acid. The greatest sap flow does not occur at the time when the most water is contained in the tree. More sap flowed at the opening of the sugar season than at the close when more water was in the tissues. There is no evidence that the water is forced into the maple trunk by root pressure at any season. Warm sunny days and freezing nights form ideal sugar weather. On good sap days the pressure from above downwards is greater than that from below upwards. The flow generally, but not always, parallels the pressure. Later in the season and upon poor sap days, upward pressure and flow exceed those from above. The fastest run of sap from a tap hole during the experiments was 17·7 c.c. per minute. Jones and Orton, using lithium chloride, had previously determined the rate of flow in either direction as 2 to 6 inches per minute.

Some observations on this subject were made during the spring on two trees, numbered respectively 185 and 3389, growing in the Botanical Garden at Ottawa. In order to determine whether the flow of sap came from the bark or the wood, several small branches on each tree were chosen which projected horizontally or inclined slightly upward. These were cut across at right angles to their length on March 1, 1923, the cut end was smoothed and the bark peeled off close to the wood for a distance of about an inch from the cut end. In tree No. 185 sap commenced to flow on April 11 and ceased on April 27, while in tree No. 3389 the respective dates were April 17 and May 14. In no instance was sap observed to exude from the cut surface of the bark. Several observations were made on the rate of flow of sap from a cut branch together with records of temperature, etc. In tree No. 185 a branch measuring 15 mm. in diameter (including the bark) was selected, while in tree No. 3389 the diameter of the branch was 18 mm. The number of drops falling per minute was counted; the diameter of each drop was about 5 mm. Some of the results were as follows:

April 19, 1923. Tree No. 185. Time, 3.40 P.M. Shade temperature = 50° F. Fifty-one drops fell in five minutes.

April 20, 1923. Tree No. 185. Time, 3.15 P.M. Shade temperature = 77° F. Sunny. Two counts gave 8 drops each per minute.

April 16, 1923. Tree No. 3389. Time, 3 P.M. Shade temperature = 38° F. Snow was still lying round the base of the tree. Sap was flowing at the rate of 18 drops in five minutes. Another count gave 17 drops in five minutes.

April 19, 1923. Tree No. 3389. Time, 3.55 P.M. Shade temperature = 50° F. Some snow still around the base of the tree. Drops were falling at the rate of 115 in five minutes. Another count gave 22 drops in one minute.

A microscopical examination of twigs cut from each tree on March 1 and on May 7, on which date the buds were swelling, showed abundant starch grains in the medullary rays but none in the pith on both occasions. The amount of water present in several small branches half an inch in diameter taken from each tree was also determined for the above dates, when it was found that each tree contained 1 per cent. less water on May 7 than it did on March 1.

The spring flow of sap was also observed in five other species of maple growing in the Botanical Garden here. In *Acer Myabei* on April 14 an icicle measuring 9 inches long and $1\frac{3}{4}$ inches wide at the base was observed hanging from a broken branch.

While some points in the metabolism of the maple sap may still be obscure, it is abundantly evident that the vessels of the wood are able to carry the sugar solution in both directions in the tree-trunk and that the rate of flow is comparatively rapid.

The Origins of the Conception of Isotopes.[1]

By Prof. FREDERICK SODDY, F.R.S.

ONE of the most important consequences of the study of the chemistry of the products of radioactive change has been the discovery of isotopes and the interpretation, in consequence, of the Periodic Law in terms of modern views of atomic structure. It is one of the few fields in the vast borderland between physics and chemistry, overrun of recent years by an advancing swarm of mathematicians and physicists, armed with all sorts of new-fangled weapons, in which the invaders have found the chemist already in possession. The broad highways they have hewn thereto are already dusty with the feet of pilgrims and are being watered by the tears of candidates for "Honours." But the somewhat intricate bye-ways through which the chemist first found his way into this virgin territory, and the views on the road before it was in sight, may still preserve something of their pristine interest.

The word *isotope* signifies "the same place," in allusion to isotopes occupying the same place in the Periodic Table. Before this word of theoretical meaning was coined, isotopes were experimentally well known as elements non-separable by chemical methods and completely identical in their whole chemical character. The analysis of the constituents of matter, to which we were born and brought up to regard as the most searching and fundamental, is an analysis by means of its chemical properties. Although, later, a new and even more powerful method—spectroscopic analysis—was developed, it merely dotted the *i*'s and crossed the *t*'s of chemical analysis, filled in a few vacant places in the Periodic Law, and handed over the newcomers to the chemist to classify along with the rest of the eighty or so "foundation stones" of which he supposed the material universe to be built up.

With the close of last century another new method—radioactive analysis—was developed, which is applicable, of course, only to the radio-elements; that is, to the elements uranium and thorium and the 34, as we now know, successive unstable products of their spontaneous disintegration. Each of these possesses a definite radioactive character; it is produced from one and changes into another element, and, in both changes, rays characteristic of the two substances are expelled, which are as fine a hall-mark of their identity as any of the "tests" of chemical analysis. But radioactive character, unlike spectroscopic character, is completely independent of chemical character. The latter might be called "existence properties," whereas the radioactive character is that attending the explosion of the atom which terminates the existence of the element as such. It provided the necessary independent method of analysis capable, for the first time, of distinguishing between elements identical chemically and occupying the same place in the Periodic Table, *i.e.* between isotopes.

THE EARLIER CHAPTER OF RADIO-CHEMISTRY.

Not a hint of this, however, was afforded by the earlier chapter of radio-chemistry. On the contrary, no development could appear more normal. Just as rubidium, thallium, etc., were detected by the spectroscope before anything of their chemistry was known, so radium was detected in pitchblende by its radioactivity in concentration thousands of times less than is necessary to show a single line of its spectrum. But with more concentrated preparations a new spectrum *was* discovered, and then a new element, which was found to possess a chemical character entirely new and sufficing for its separation in the pure state from all other elements. As in the case of the elements discovered by the spectroscope, radium was found to occupy a place, hitherto vacant, in the Periodic Table. But, as it happened, radium is exceptional in this. Its chemical character was quite normal, and indeed could have been largely predicted beforehand for the missing element occupying this place. The development of the subject showed it to be but one of some 34 radio-elements formed from uranium and thorium. But there are not 34 vacant places in the Periodic Table to accommodate them.

META-ELEMENTS.

So far as I am aware, there is no anticipation, prior to the systematic study of the chemistry of the radio-elements, of the idea that there may exist different elements with absolutely identical chemical character. Sir William Crookes, it is true, once thought, though the idea has not survived more extended examination, that the properties of the elements, as we know them, might be a mean value, and that the individual atoms composing the element might differ in weight and chemical character continuously on either side of this mean. If so, more refined methods might serve to resolve the element into a collection of what he termed "Meta-elements," possessing the main character of the original, but differing from one another to a slight extent. Misled by the phosphorescence spectra, which are now known to be characteristic of mixtures rather than chemically homogeneous substances, he thought at one time that he had been successful in so resolving yttrium. But the present idea, that elements may exist absolutely the same in chemical nature and yet absolutely different in other properties, such as radioactivity and atomic weight, is totally distinct from this.

THE EXPERIMENTAL METHOD THAT FIRST REVEALED ISOTOPES.

I venture to think that no more elegant extension of our methods of gaining new knowledge has ever been obtained than that which, in due course, was to reveal the existence of isotopes. The original observations, upon which the theory of atomic disintegration was first founded, were that thorium is continuously producing a new radioactive substance, thorium X, separable from it by precipitation with ammonia but not with other precipitants, and, after separation, continuously re-forming again. The thorium X was short-lived and changed again into a gas, the thorium emanation, for which the name *thoron* has recently been proposed, which was even shorter-lived and changed again to a solid—the "excited activity" now known

[1] Discourse delivered at the Royal Institution on Friday, May 4.

as the active deposit—which again went through further changes. The rays resulted from these successive changes, α-rays in the first and α-, β-, and γ-rays in the last changes. Below is the first part of the thorium disintegration series as it appeared to Sir Ernest Rutherford and myself in 1903:

$$\text{THORIUM} \xrightarrow{\alpha} \text{THORIUM X} \xrightarrow{\alpha} \text{THORON} \xrightarrow{\alpha}, \text{etc.}$$

In 1905 Sir William Ramsay and O. Hahn were engaged in extracting radium from thorianite, a new Ceylon mineral containing both uranium and thorium in important quantity. The radium was separated with the barium, and the chlorides fractionated in the usual way. They found a new radio-element to be present and to be separated from the radium with the barium. It proved to be the direct parent of thorium X, and intermediate in the series between the latter and thorium, and they called it radiothorium. In spite of this easy and apparently straightforward separation, the experience of a number of chemists showed that something remained to be explained, for it was found to be difficult to the verge of impossibility to separate radiothorium from thorium. Ramsay and Hahn had in fact "separated" isotopes in 1905, for radiothorium and thorium are isotopes. Yet further work has shown the two to be so alike that no separation by chemical means is possible!

Then in 1907, along with the radium which had been separated from thorianite, Hahn discovered another new radio-element, mesothorium, the direct parent of radiothorium and intermediate between it and thorium. In the next year he showed that mesothorium consists of two successive products—the first, the direct product of thorium, mesothorium 1, being practically rayless and generating a short-lived product, mesothorium 2, giving powerful β- and γ-rays.

This resolved the mystery, and one cannot do better than to quote the words of McCoy and Ross (J. Amer. Chem. Soc., 1907, 29, 1709).

> "Our experiments strongly indicate that radiothorium is entirely inseparable from thorium by chemical processes. . . . The isolation of radiothorium from thorianite and from pure thorium nitrate . . . may have been accomplished by the separation of mesothorium which in time changed spontaneously into radiothorium."

Thus the radiothorium separated from the mineral thorianite by Ramsay and Hahn was not the radiothorium *in the mineral*, but that subsequently produced from the easily separated mesothorium, after it had been removed from the thorium. If they had fractionated the radium-mesothorium-barium mixture at once they would not have discovered radiothorium. The lapse of time after the separation of the mesothorium is essential. Nowadays many non-separable radio-elements are, like radiothorium, "grown" from their separable parents. Thus radium D, an isotope of lead, is grown from the radium emanation (radon), although it cannot be separated from the mineral, which always contains lead in quantity.

The first part of the thorium series now runs [2]

$$\underset{2\cdot10^{10}\text{ years}}{\text{THORIUM}} \xrightarrow{\alpha} \underset{9\cdot67\text{ years}}{\text{MESOTHORIUM 1}} \longrightarrow \underset{8\cdot9\text{ hours}}{\text{MESOTHORIUM 2}}$$

$$\xrightarrow{\beta} \underset{2\cdot91\text{ years}}{\text{RADIOTHORIUM}} \xrightarrow{\alpha} \underset{5\cdot25\text{ days}}{\text{THORIUM X}} \xrightarrow{\alpha} \underset{78\text{ seconds}}{\text{THORON}} \xrightarrow{\alpha}, \text{etc.}$$

In this series thorium and radiothorium and mesothorium and thorium X are two pairs of isotopes. If we represent the successive products by balls of different colours to indicate their chemical character, isotopes being of the same colour, chemical analysis will sort the balls into their different colours, and the lapse of time will cause some of the colours to change. The ball representing mesothorium will in time turn into that representing radiothorium, so that the latter, before indistinguishable from thorium, becomes known as a separate individual.

The Isotopes of Uranium.

It will be noted that the method of separating isotopes depends upon their being alternate rather than successive in the series. If radiothorium had been the direct product of thorium, the two would to this day never have been separated. The changes of chemical character are, as we shall later see, intimately connected with the electric charges on the α- and β-particles expelled. For successive products to have the same character, no rays, or at least no charged particles, must be expelled. It is always as well, and no subject illustrates the point better than that of isotopes, to reflect not only upon what our methods are able to reveal but also upon what they could not reveal.

At first it seemed that uranium itself was a case of successive isotopes. Boltwood in 1908 proved from his study of the relative activities of the successive products giving α-rays in minerals, that whereas all of them, except uranium, gave off only one α-particle per atom disintegrating, uranium gave off two. By direct observation with the scintillation method it was proved that the two α-particles from uranium are *not* simultaneously expelled, and later it was shown that they possess different velocities. If the slower comes from uranium itself (uranium I), the period of which is known to be $6\cdot10^9$ years, the swifter must come from the isotope (uranium II), and its period must be some three million years. This is an example of isotopes being revealed by difference of radioactive nature simply, though no other evidence of their separate existences is available. Owing to the long periods of the α-ray-giving members of the early part of the uranium series, it has been much more difficult to unravel than the thorium series. As a result of researches too numerous to detail, it has been concluded that the main series is almost entirely analogous to the thorium series and runs

$$\underset{6\cdot10^{9}\text{ years}}{\text{URANIUM I}} \xrightarrow{\alpha} \underset{35\cdot5\text{ days}}{\text{URANIUM X}_1} \xrightarrow{\beta} \underset{1\cdot65\text{ minutes}}{\text{URANIUM X}_2} \xrightarrow{\beta} \underset{3\cdot10^{6}\text{ years}}{\text{URANIUM II}}$$

$$\xrightarrow{\alpha} \underset{10^{5}\text{ years}}{\text{IONIUM}} \xrightarrow{\alpha} \underset{2\cdot440\text{ years}}{\text{RADIUM}} \xrightarrow{\alpha} \underset{5\cdot55\text{ days.}}{\text{RADON}} \xrightarrow{\alpha}, \text{etc.}$$

Though two short-lived products probably intervene between the two uraniums, analogous to the two mesothoriums between thorium and radiothorium, the relation of their period to that of their product, uranium II, is so hopelessly unfavourable that there is no hope of ever being able to put the separate existence of uranium II into evidence in the same way as was done

[2] The periods shown in the second line are the periods of average life of the successive products. These are 1·443 times the period required for one-half of the element to change.

for radiothorium. For all *practical* purposes the two uranium are as non-separable by this method as if they were actually successive products. I spent many years, before this part of the series was at all well known, looking for the product of uranium X, and separated this constituent from 50 kilograms of uranium nitrate repeatedly in the attempt. I was looking for a growth of α-rays concomitantly with the decay of the β-rays of the uranium X. If the product had been ionium, as at first thought $(\mathrm{UI}\xrightarrow{\alpha}\mathrm{UII}\xrightarrow{\alpha}\mathrm{UX}\xrightarrow{\beta}\mathrm{Io}\xrightarrow{\alpha})$, it should have been just possible to detect it; but since it is the 30 times longer-lived uranium II, the attempt is hopeless, especially as uranium X and ionium are isotopes, and therefore the uranium X separated must always possess a certain initial α-activity due to ionium.

THE ABSOLUTE CHEMICAL IDENTITY OF ISOTOPES AND ITS IMPLICATIONS.

The years 1908–10 were productive of many prolonged and serious efforts to separate isotopes by chemical means. In 1908 Boltwood discovered ionium and showed that it resembled thorium. Keetman, who with Marckwald discovered ionium independently, tried twelve good methods all known to be effective in the purification of thorium in the attempt to separate the ionium from thorium, completely without success. Auer von Welsbach, on a technical scale, separated the ionium and thorium from 30 tons of pitchblende and tried fresh methods in the hope of separating them, but failed. It was with this preparation that Exner and Haschek tried without success to find the ionium spectrum; and Russell and Rossi confirmed their result, that the spectrum of ionium was that of pure thorium. When later I had determined beyond doubt, from measurements of the rate of growth of radium from uranium, that the period of ionium was 100,000 years, and that Welsbach's preparation must have been approximately 30 per cent. ionium and 70 per cent. thorium by weight, it followed that the spectra of isotopes must, like their chemical character, also be identical. The difference, if any exists, is almost beyond the limit of detection by the most powerful methods.

Similarly, the chemical identity of radium D and lead was established as a consequence of very prolonged and refined chemical examination. Paneth and Hevesy established upon this their well-known method of using radioactive isotopes as indicators for elements in too small quantity to be dealt with except by such methods. On the principle that wherever the radioactive element is there will its inactive isotope be also, provided that they have once been properly mixed, many difficult or uncertain chemical analyses may be converted into simple radioactive ones.

In 1909 Strömholm and Svedberg made what was probably the first attempt to fit a part of the disintegration series into the Periodic Table, and although the effort in itself was in an important respect erroneous, in their paper is to be found the first anticipation that the chemical non-separability found for certain pairs and groups of radio-elements may also apply to the non-radioactive elements. Remarking on the fact that there are three parallel and independent radioactive series, they suppose this to proceed down through the Periodic Table, "but that always the three elements of the different genetic series, which thus together occupy one place in the Periodic System, are so alike that they always occur together and also have not been able to be appreciably separated in the laboratory." They point out also, this idea would explain the exceptions to the Periodic System "if the elements of the scheme were mixtures of several homogeneous elements of similar but not completely identical atomic weight."

In the next year I arrived independently, and without in the least postulating any continuance of the genetic series beyond the radio-elements, at a similar view. Marckwald and I found independently that mesothorium 1 was chemically similar to radium, a fact undoubtedly known to Hahn and those engaged in the technical extraction of mesothorium, but kept secret. It was known from some work of Boltwood that precipitating barium sulphate in a solution containing mesothorium removes it, but it was thought that the action of the barium sulphate was similar to that in removing uranium X, for which it had long been used, namely, a simple adsorption. I was surprised to find it absolutely different. The removal of the barium from the mesothorium, as from radium, could only be accomplished by the fractional crystallisation of the chlorides. In this fractionation the radium and mesothorium remained together and behaved as a single element. Within the limit of error of the most careful radioactive measurements, there was no change in the relative proportion of the two elements at the end of the process from that in which they exist in the original mineral.

Chemistry has many cases of elements similar in chemical character, but nothing approaching this. For we know, beforehand, that we are dealing with a mixture of two substances and can estimate accurately the proportion of each individual. Yet to all chemical operations they behave as a single substance. The differences of atomic weight are considerable, two units in the cases of mesothorium and radium, and of ionium and thorium, and four units in that of radiothorium and thorium. It was certain that if isotopes existed in the case of the ordinary chemical elements the absence of a second radioactive nature independent of the chemical nature would make it impossible for them to have been recognised. Hence the implication followed that any supposed element may be a mixture of several chemical identities of different atomic weight, and any atomic weight might be merely a mean number (Ann. Reports, Chem. Soc., 1910, 286). There is an element of tragedy in this. The lifetime labours of the chemists who, since the time of Stas, have devoted themselves to the exact determination of atomic weights appear to have as little theoretical interest now as if you sought to determine the average weight of a collection of beer bottles, all exactly alike but not all quite full.

THE RADIO-ELEMENTS AND THE PERIODIC LAW.

The years from 1911–13 were crowded with important advances, and to do the exact history justice would take an undue share of the available time. In 1911 the chemistry of most of the α-ray-giving members was sufficiently known for it to be seen

that the expulsion of the α-particle caused the element expelling it to move from the place it occupied in the Periodic Table to the next place but one to it in the direction of diminishing mass.

At this time the chemistry of the post-emanation members had scarcely been studied, though von Lerch, from electrochemical researches, had put forward the rule that the successive products are each electrochemically "nobler" than the last, a rule which describes well enough the electrochemical behaviour of the first three—the A to C members, as they are called. Then, as a result of the experiments of Schrader and Russell, it was found that their volatility was much affected by chemical treatment and by the atmosphere in which they were volatilised. Thus, in hydrogen, radium C volatilises at as low a temperature as 360° C., though, in air, a temperature of 1200° is necessary. This clearly indicated the possibility that even these excessively ephemeral elements have a definite chemical character. Hevesy showed, by electrochemical methods, that the three B-members are identical in properties among themselves, and also the three C-members.

But the work which, more than anything else, served to reveal, as in a flash, the simple and sweeping generalisation which covers the evolution of the radioactive elements was that of A. Fleck in my laboratory in Glasgow. He studied the chemistry of the various members, still uncharacterised, from the definite point of view of ascertaining to which element each most closely approximated in chemical character, and then whether it was separable from that element or not. In addition to confirming more rigorously many conclusions already reached, he proved that mesothorium 2 was non-separable from actinium, the three B-members from lead, like radium D, and the three C-members and radium E from bismuth.

Hevesy and Russell—the first with regard to the valency of the radio-elements and the second with regard to the positions they occupy in the Periodic Table—published early in 1913 statements of the full law underlying radioactive evolution, but only in part correct. Within a month K. Fajans, in Carlsruhe, published the scheme correct and complete, including the complicated branchings that occur at the C-members. In a paper, amplifying and amending Russell's scheme, I arrived independently at the same scheme as Fajans. Each α-ray expelled causes a shift of two places in the Periodic Table in the direction of diminishing mass, and each β-ray a shift of one place in the opposite direction. In its present form the scheme is shown in Fig. 1. The chief uncertainty remaining is whether the actinium branch starts from uranium II, as shown in the figure for convenience, or from uranium I, or even from a third independent isotope of uranium. So that the atomic weights shown for the actinium series are purely provisional.

By the consistent application of the two rules mentioned, the members found to be non-separable from one another fall in the same place in the Periodic Table. The chemical character has nothing to do with the radioactivity, nor with the series to which the element belongs, nor with its atomic weight. It depends upon a number, now called the atomic number, shown at the top of the place in the figure.

Before passing on to this, the chief practical consequences of the generalisation may be briefly enumerated.

(1) Of the members still uncharacterised, the A and C′ members must be the isotopes of polonium (radium F) and radium C_2 (now called radium C″), actinium D and thorium D must be isotopes of thallium. Fleck at once verified these predictions as regards radium A, actinium D, and thorium D.

(2) Uranium X, like mesothorium, must consist of two successive β-ray-giving products, intermediate between the two uraniums. Fajans and Gohring at once succeeded in separating from uranium X a very short-lived product, uranium X_2, giving the more penetrating of the two types of β-ray expelled, the uranium X_1 giving the less penetrating β-rays.

(3) The parent of actinium in the IIIrd family must be an isotope of radium, if actinium is formed in a β-ray change—a conclusion I at once experimentally disproved—*or* it must be an isotope of uranium X_2, in the Vth family, if actinium is formed in an α-ray change. This was proved by Cranston and myself, and the name "eka-tantalum" given to the new element, and by Hahn and Meitner, who named it protoactinium. It is linked to uranium through uranium Y, a branch member discovered by Antonoff in 1911, and suspected to be in the actinium series.

Protoactinium, to give it Hahn and Meitner's name, has been shown by them to give α-rays and to be chemically so like tantalum that hitherto it has not been separated from it. Its period is about 17,000 years, and from this it may be calculated that there is about one-fifth as much of it by weight in minerals as there is of radium. This may be sufficient to enable it to be isolated, and for its spectrum, atomic weight, and chemical character to be ascertained. The branch series runs

$$\underset{\mathrm{VI}}{\mathrm{U}} \xrightarrow{\alpha} \underset{\mathrm{IV}}{\mathrm{UY}} \xrightarrow{\beta} \underset{\mathrm{V}}{\mathrm{Pa}} \xrightarrow{\alpha} \underset{\mathrm{III}}{\mathrm{Ac}} \longrightarrow \underset{\mathrm{IV}}{\mathrm{RaAc}} \xrightarrow{\alpha} \underset{\mathrm{II}}{\mathrm{AcX}} \xrightarrow{\alpha} \underset{0}{\mathrm{An}} \xrightarrow{\alpha}, \text{ etc.}$$

in which the figures in the second line refer to the family in the Periodic Table to which the element belongs.

(4) All the ultimate products in all branches are isotopes of lead. The atomic weight of the two products of thorium are both 208, and of the major branch of uranium 206. As is well known, this had only to be tested to be proved correct. The atomic weight of the lead from the purest thorium minerals is as high as 207·9, and of that from the purest uranium minerals 206·0. The spectra of these isotopes, but for the infinitesimal difference already alluded to, are identical. But the densities are proportional to their atomic weights. This was a very simple prediction I made, before testing it, from the theoretical views about to be dealt with.

The Theoretical Interpretation of Isotopes.

The results on the theoretical side were no less definite and important, and isotopes found a ready explanation on the nuclear theory of atomic structure put forward in a tentative form by Rutherford in 1911. This theory accounted for the large angles through which occasional α-particles were deflected in their

passage through atoms, by the existence of a very minute highly charged nucleus at the centre of the atom, the rest of the atom being occupied by separate charges of opposite sign equal in number to the nuclear charge. For such an atom scattering should be proportional to the square of the nuclear charge. Experiment showed that scattering was approximately proportional to the square of the atomic weight. So that it looked as if, as in the α-particle itself, there existed one unit of nuclear charge to each two units of atomic weight. This would make the nuclear charge of uranium of atomic weight about 240, 120+.

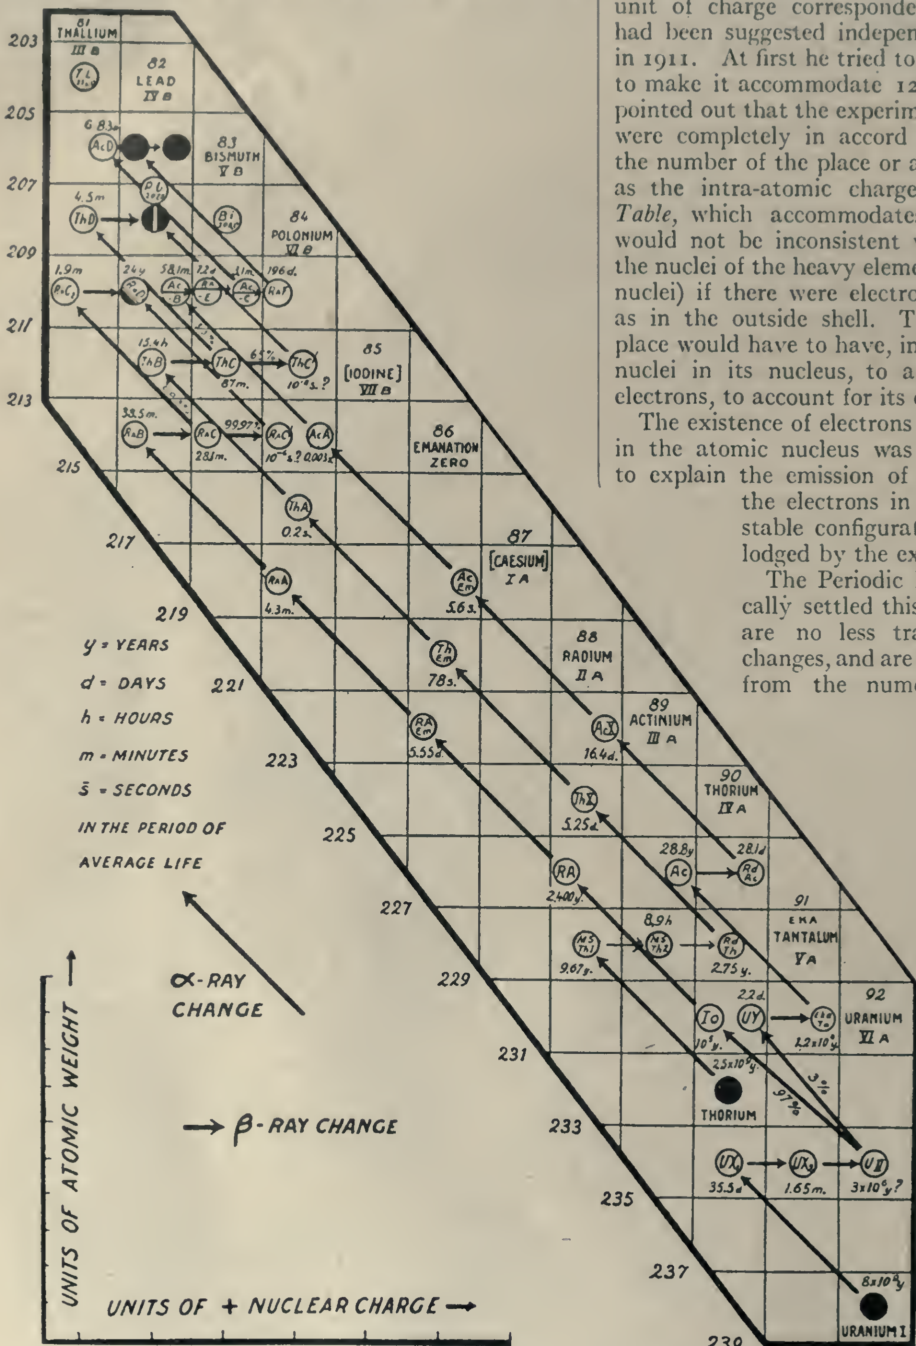

FIG. 1.—Radio-elements and the periodic law. All elements in the same vertical column are isotopes.

Since the α-particle carries two positive charges and the β-particle one negative, the obvious inference from the figure is that the successive places in the Periodic Table correspond with unit difference in the intra-atomic charge. This view, and also that each unit of charge corresponded to two units of mass, had been suggested independently by van der Broek in 1911. At first he tried to stretch the Periodic Table to make it accommodate 120 places. But in 1913 he pointed out that the experimental results for scattering were completely in accord with his own view (that the number of the place or atomic number is the same as the intra-atomic charge) *on the existing Periodic Table*, which accommodates some 90 elements. It would not be inconsistent with his other view (that the nuclei of the heavy elements are made up of helium nuclei) if there were electrons in the nucleus as well as in the outside shell. Thus uranium in the 90th place would have to have, in addition to the 60 helium nuclei in its nucleus, to account for its weight, 30 electrons, to account for its charge of 90+.

The existence of electrons as well as positive charges in the atomic nucleus was also postulated by Bohr to explain the emission of β-rays, for on his theory the electrons in the external shell form a stable configuration and could only be dislodged by the expenditure of work.

The Periodic Law generalisation practically settled this question. β-ray changes are no less transmutational than α-ray changes, and are sharply to be distinguished from the numerous processes, such as friction, chemical change, action of ultra-violet light, and incandescence, during which electrons are detached from atoms. The effect on the chemical character produced by the expulsion of one α-particle is exactly undone by the expulsion of two β-particles, and the product becomes isotopic with the original parent. This means that both α- and β-particles must be expelled from the nucleus and that isotopes are elements the atoms of which have the same *nett* nuclear charge; *i.e.* the same excess number of positive over negative charges in the nucleus, but different numbers of positives and negatives reckoned separately. For such systems the electronic shell would be identical, and so the identity of the chemical and spectroscopic character is explained. Also the atomic volume is the same; that is, the density must be proportional to the atomic weight.

We were able to get an interesting confirmation of this view. In the change of uranium X_1 to uranium II

two electrons are lost as β-rays. In the oxidation of a uranous salt to a uranic or uranyl salt two electrons are also lost,

$$U^{++++} = U^{++++++} + 2E.$$

If these come from the same region of the atom as the β-particles, then uranous salts, so long as their valency does not change, should be like uranium X_1, chemically non-separable from thorium. Fleck, trying this, found great similarity in chemical properties between uranous salts and thorium, but not identity. He was able to separate them by chemical methods without changing the valency of the uranous salt.

The great merit of the nuclear atom from the chemist's point of view was that it afforded for the first time a clear picture of the difference between a chemical and a transmutational (or radioactive) change. The latter occur in the nucleus and are irreversible. The external shell accommodates itself instantly to the change of the nucleus. But any change suffered by the external shell (chemical change) has no effect on the nucleus, which always acts so as to make the external shell conform to one most stable configuration.

The atom is an *imperium in imperio*, and like most such systems is very conservative and resistant to change. The electrons in the shell, that govern almost all the atomic properties, except mass and radio-activity, are in turn but the bureaucratic instruments of the real government, which is the intensely charged central nucleus. The transmutation of atoms, as of social systems, is alike impossible because the apparent government is not the real government. Rutherford's experiments on the bombardment of atoms by α-particles show that only about one out of a hundred thousand of the latter, in passing through hydrogen, ever hits a hydrogen nucleus, and the proportion of hits to misses is something like one in a thousand millions. In politics, contrasting the number of missiles hurled with the results achieved, the shooting seems even worse. It is only when the atomic or social systems break up or break down that we learn even of the existence of their real internal constitution.

Current Topics and Events.

ON July 30 there was read a third time in the House of Lords the Wild Birds Protection Bill introduced by Viscount Grey of Fallodon. The Bill aims at the repeal of existing enactments on the subject, and at substituting new provisions on lines recommended in 1919 by a Departmental Committee. The measure appears to us to be a wise one which should be welcomed by ornithologists and other bird lovers and also on grounds of economic importance. More than this, it is a much stronger measure than any of its predecessors, and if it become law and be properly enforced it should give a much more effective protection than is at present possible. The important new powers are those which are to make it an offence to be in possession of any bird, part of a bird, nest, or egg which may be presumed to have been illegally taken, and those which are to place the onus of proof on the possessor. At present, on the other hand, the onus is on the prosecution, and the act of killing or taking is the material fact to be proved: as a result, the skins and eggs of protected birds can be offered for sale with impunity by taxidermists and dealers, and "plovers' eggs" are freely sold in shops and restaurants in the close season. The Bill has still to be passed by the House of Commons, but we hope that this may be successfully accomplished next session.

AUGUSTIN LE PRINCE has rarely been recognised as one of the pioneers in kinematography. Mr. E. Kilburn Scott, who knew him personally, recently lectured before the Royal Photographic Society on his work in this direction, and a report of the lecture is given in the current number of the Society's Journal. Mr. Scott considers it established that Le Prince was the first to make a successful camera to take photographs at more than 16 in a second, was the first to show moving pictures on a screen (at Leeds in 1889), was the first to appreciate the importance of using flexible film (he is stated to have used celluloid films before September 1890), and was the first to use perforations and sprocket wheels (patents dated 1888). Le Prince's career came to an extraordinary end. He was last seen on September 16, 1890, at Dijon, entering a train for Paris, but since then nothing whatever seems to be known of him. One suggestion was that he might have been kidnapped by agents of American inventors whom he had forestalled.

THE Royal Geographical Society of Australasia (Queensland) is contemplating the investigation of the problems of the Great Barrier Reef, and is inviting other scientific societies and the universities of Australia to co-operate. In the *Queensland Geographical Journal* for 1920–22 Prof. H. C. Richards indicates some of the problems that await solution, and shows by a sketch of previous work on the subject how divergent are the views expressed on some important points. For example, it is apparently not known if the Great Barrier Reef is rising or falling or is in a static condition. The suggested investigations would include complete charting, including making vertical sections, of at least three island points on the reef, one each in the northern, middle, and southern regions, and recharting at intervals of a decade; charting of several of the more important troughs or valleys in the reef and the lagoon area, and recharting, also, at intervals of a decade; complete survey of the fauna, flora, and economic resources; and experiments on the growth of corals under varying conditions.

A COPY of a pamphlet has reached us on "Suggestions for the Prevention of the Decay of Building Stone," by Mr. J. E. Marsh (Basil Blackwell, Oxford, 1s. 6*d*. net). The author remarks in the preface: "In 1861 the Commission, appointed to stop the decay in the stone of Westminster Palace, decided to wait till a remedy had been discovered, and did not expect to have to wait long. We have waited sixty

years and seem to be no nearer a solution of the problem. . . . The preservation of our old historic buildings is a matter of as much concern now as it has ever been. Suggestions however slight may help. That is why this pamphlet has been written." Sections are given on Parliamentary commissions on the subject, theories of stone decay, and the treatment of stone, and the author describes experiments which he has carried out. The final sentences of the booklet are worth quoting: "The simple remedy is to keep the stone sterile. . . . This means, in simple language, keeping the stone clean. Alkalies have been used as cleansers from time immemorial. The walls of Oxford are sick; they have been drugged, but they have not been cleaned. What they need more than drugs is a good wash; for dirt rather than time is the destroyer of things."

Bergens Museums Aarsberetning for 1921–22 records the gift by the heirs of Herman Friele of that distinguished naturalist's cabinet of mollusca, mainly collected by him in the neighbourhood of Bergen, but also, in company with G. O. Sars, from northern Norway. It comprises in addition authentic specimens from the Atlantic and adjacent seas received in exchange from the leading specialists of his day. The number of specimens is 1650. This report also announces the commencement of work at the new biological station erected on the island of Herdla, 27 kilometres north-west of Bergen, where Herlö-fjord branches off from Hjelte-fjord, in a region already classic through the researches of Michael Sars. The station is provided with a small research sailing vessel, the *Herman Friele*, of 23 tons gross tonnage, with auxiliary oil-motor power.

THE University of Frankfort-on-Main has established an Institute with a professorship which is to deal with the applications of physics in medicine, *e.g.* radioactivity, X-rays, light rays, and the like. It is stated to be the first institute of the kind to be established in Germany.

THE Research Department of the Calico Printers' Association, Ltd., St. James's Buildings, Manchester, invites application for the post of a physicist whose duties will be to conduct research on physical problems arising in the calico-printing industry. The person appointed will work in association with the chemical research staff.

THE following are among the Civil List pensions granted during the year ended March 31: Miss A. H. Bacot, in recognition of the services rendered by her brother, the late Mr. A. W. Bacot, to science and to the nation, 75*l.*; Mrs. M. Barnwell, in recognition of the services rendered by her father, the late Dr. H. Woodward, to the cause of geological science, 25*l.*; Lieut.-Col. H. H. Godwin-Austen, in recognition of his services to science and to the nation, 100*l.*; Mrs. M. Lyster Jameson, in recognition of the services rendered by her husband, the late Dr. H. Lyster Jameson, to science, 50*l.*

BY the will of the late Mrs. Bacon, of New York, the Smithsonian Institution of Washington has received a sum of 10,000*l.* for the establishment of a travelling scholarship for the study of the fauna of countries other than the United States, in memory of her husband, Walter Rathbone Bacon. The scholarship will be tenable for at least two years, and the annual value about 500*l.* Applications for the award must include details of the proposed research, the benefits to be expected from it, the estimated cost, and full particulars of the scientific and physical qualifications of the candidate; they should reach the secretary of the Smithsonian Institution not later than October 1.

MR. J. S. HUXLEY informs us that, by an oversight, his name was omitted from the list of signatories to the letter on the forthcoming *British Journal of Experimental Biology* which appeared in NATURE of July 28, p. 133.

THE July issue of *The Fight against Disease*, the organ of the Research Defence Society, contains the report of the Committee for the year, and an abstract of Dr. Saleeby's lecture on sunlight and disease, with photographs of patients at Rollier's "sunlight school" at Leysin. Notes on smallpox and vaccination also occupy considerable space.

WE have received the twelfth report of the Microbiological Laboratory, N.S. Wales, for the year 1921. It contains a useful list of the species of fleas that occur on native rats. In some instances species of fleas appear to occur on marsupials and rodents indiscriminately. Some observations are also recorded on the Sydney milk supply, which on the bacteriological results seems to be of very poor quality. It is to be hoped that the publication of this annual report may be expedited in the future.

BULLETIN No. 25 of the Institute of Science and Industry, Australia, deals with "The Manufacture of Pulp and Paper from Australian Woods." The book itself is printed on paper made by the Institute in the course of the experiments described; a few sample sheets of paper of varying composition are also bound in at the end. The Bulletin is divided into five parts: General information; investigations (prior to 1920); laboratory investigations; semi-commercial experiments; economics.

WE have received a copy of the Nobel Lecture, "The Origins of the Conception of Isotopes," delivered by Prof. F. Soddy at Stockholm last December. This is a clear account of the development of radioactivity from its discovery by Becquerel in 1896 down to modern times. The conception of isotopes dates from 1905, though their complete chemical identity was not recognised until two years later. This identity was afterwards extended to include their electrochemistry and their spectra, but more recently infinitesimal differences have been found in the latter.

BULLETIN 53 S, issued by Messrs. Watson and Sons, Sunic House, Parker Street, Kingsway, London, illustrates the various medical uses to which high-frequency currents may be put. Use is made of the term violet-ray treatment; no doubt violet rays issue from the glass electrodes holding the gas under discharge, but it is open to question whether it would

not be better to retain the use of the term high-frequency treatment until it is definitely proved that the beneficial effects are due to the radiation. A large variety of electrodes suitable for the cavities and other parts of the body is illustrated, and instructions are detailed for their use.

THE British Medical Association (429 Strand, W.C.2) has published and issued a useful "Handbook for Recently Qualified Medical Practitioners" (price 2s. 6d. net). It gives concise but clear details of the duties of medical practitioners and of the legal obligations (by Dr. W. A. Brend) placed upon registered practitioners. The main careers open to members of the medical profession are summarised, and a section is devoted to post-graduation study and special diplomas. A section deals with the British Medical Association and its work, and the Dangerous Drugs Regulations are printed in an appendix.

PUBLICATION No. 110 of the Koninklijk Nederlandsch Meteorologisch Instituut is an important contribution to the oceanography of the Atlantic. It is a summary of about two and a quarter millions of observations made by steamers and sailing ships during March, April, and May throughout the period 1856–1920. There are 186 pages of tables and an atlas, with 24 plates. These represent currents, winds, the general circulation of the water and air, isobars, the general courses of water and air isotherms, and the limits of ice, fogs, etc. The tables were published in 1921 and the plates in 1922.

RECENT fishery publications include two papers from the Ministry of Agriculture and Fisheries ("Fishery Investigations"; Ser. II. vol. v., Nos. 5 and 6). No. 5, by Dr. W. Wallace, is a report on experimental hauls with small trawl nets made in the shallow waters of the North Sea in the years 1904-1912. No. 6 deals with the plankton collected during special cruises made in 1920-21 in order to estimate the annual production of plaice ova. The report is prepared by Mr. R. E. Savage. An important report (in continuation of earlier ones) on the life-history of the mackerel is contained in vol. xxx. of the reports (issued by the International Council for Fishery Investigations). This paper is the work of Dr. E. Ehrenbaum, of the Natural History Museum in Hamburg.

WE have received from the Eastman Kodak Company of Rochester, New York, the fifth volume of the "Abridged Scientific Publications from the Research Laboratory" of the Company. Owing to the increasing number of publications it has been decided to issue these volumes annually, and the present volume deals with the papers which were published during 1921. The abridgments are, of course, somewhat condensed as compared with the original papers, to which any one actually working at the subject dealt with would naturally refer, but for almost every purpose the abridgments will probably be found advantageous. Twenty-three communications are given in 172 pages, and there are added indexes of authors and subjects. This series of volumes forms a most valuable record of the activities of the Company's Research Laboratory, and incidentally a good indication of the general trend and progress of scientific photographical investigation throughout the world.

DR. G. ARNOLD's report as curator of the Rhodesia Museum, Bulawayo, for 1922, announces the completion of the new wing and the transference to it of the zoological collections and part of the ethnological material, thus freeing space for economic exhibits in the old building. As a result of Dr. Arnold's monograph on the sandwasps of the Ethiopian Region, the types of 70 new species have been added to the collection, a number that probably will be doubled. There are also accessions of type-specimens among bees, beetles, and Neuroptera, as well as the syntype of *Tangasaurus mennelli*, a lizard-like reptile from beds of Karroo age in Tanganyika Territory. Examination of the previously reported Codrington collection of ethnological objects has brought to light nine ceremonial staves of chiefs, from Kasembe's stronghold, such as could no longer be obtained to-day. Five Bantu spears with copper blades are evidence that the Bantu were more than capable of producing the metal weapons found at Zimbabwe. A female Bantu skeleton, found in an ancient mine-working near Gwanda, Southern Rhodesia, has been studied by Sir Arthur Keith, who considers it to date back 800 years or more. It will be seen that this report, though brief, indicates a great deal of good work.

MESSRS. ROSS LTD., optical instrument makers, have been awarded the diploma of the Grand Prix at the International Exhibition of Photographic Optics and Kinematographs held recently at Turin.

THE lectures delivered by Sir J. J. Thomson in April last on "The Electron in Chemistry," before the Franklin Institute, are being published singly in the Journal of the Institute. The complete series will shortly be published in book form under the title "The Electron in Chemistry."

IT is announced by Messrs. Longmans and Co. that the new edition of Thorpe's "Dictionary of Applied Chemistry," which is now in course of publication, will extend to seven volumes, and that a large part of the concluding volume will be devoted to an index to the complete work.

THE latest catalogue (No. 449) of Mr. F. Edwards, 83 High Street, Marylebone, W.1, is devoted to books, engravings, and paintings relating to the Indian Empire, and gives particulars of some 646 items, including geography and travel, ethnology, natural history, antiquities, etc. Among the works listed is "Annals of the Royal Botanic Garden, Calcutta," vols. 1 to 8.

MESSRS. W. HEFFER AND SONS, LTD., Cambridge, have in the press a translation of "The Internal Secretion of the Sex Gland," Prof. A. Lipschütz, with a foreword by Dr. F. H. A. Marshall. The work will give an account of the recent experimental work

of Prof. Steinach and others on the reversibility of the sexes, the part played by the interstitial gland, and the results of the transplantation of this organ.

AMONG the books shortly to be published by the Cambridge University Press we notice "Stories of Scientific Discovery," by Mrs. D. B. Hammond, consisting of short biographical sketches of Priestley, Lavoisier, Count Rumford, Herschel, Fabre, Faraday, the Curies, Darwin, Wallace, and Pasteur; vol. 4 of the "Cambridge Medieval History," dealing with the Eastern Roman Empire (717–1453), and "Foundations of Agricultural Economics," by J. A. Venn; the aim of the latter is to give some account of the origin and incidence of the numerous economic problems which affect the agricultural community.

Our Astronomical Column.

AN OFT-RECURRING RELATIVITY BLUNDER.—Many people have been temporarily misled by a fallacy in considering the Einstein bending of rays of light. They imagine that it ought to produce a sensible shift in the position of the further component of a double star, owing to its light passing close to the nearer component, or similarly that the satellites of Jupiter ought to undergo the shift at the time of occultation. Another form of the fallacy is put forward by M. de Saussure in *Astr. Nachr.* No. 5235, in an article entitled "Influence de la déviation des rayons lumineux sur la valeur du diamètre du soleil." He notes that the light from each limb of the sun would be subject to the Einstein bending, but that since it has only traversed half the gravitational field as compared with a star behind the sun, the bending at each limb is $1·75''/2$. So far he is correct. His error comes in when he asserts that the true diameter of the sun is $1·75''$ less than that measured, equivalent to 1300 km. In fact we only see the full Einstein shift when the distance from the eye to the place of bending is small compared with the distance from the eye to the object viewed. This is obviously the case for a star near the sun, but not for the components of a double star, for Jupiter's satellites or for the sun's limb.

Since the Einstein bending is similar to refraction we can easily see the fallacy by the following example. Take a bowl 6 inches deep, and let a mark on the bottom be just brought into view to an eye placed horizontally behind the edge of the bowl, when the latter is filled with water. Then the mark is seen deflected through some 41·4° from its true place. But if the eye be placed a mile away, still in the same level, the deflection is no longer 41·4° but only $19·5''$. Similarly in the case of the sun's limb, the principal bending takes place near the sun, and the enlargement of the sun's diameter is not $1·75''$ but only about $0·01''$; practically a negligible quantity.

SPECTROSCOPIC PARALLAXES.—The Memoirs of the R.A.S., vol. 62, contains a valuable paper by Mr. W. B. Rimmer on the spectroscopic parallaxes of 500 stars, the types of which range from Fo to Mb. The spectra were photographed at the Norman Lockyer Observatory, Sidmouth, with the 12-inch prismatic camera formerly belonging to Dr. F. McClean; a few of his spectrograms with the same instrument are also discussed. The differences of line-intensity were measured by the wedge extinction method devised and recently described by Dr. Lockyer. A special study was made of the means for obtaining uniform results, and cases of discordant readings were remeasured. A search has been made for additional pairs of lines suitable for the purpose, besides those used at Mt. Wilson; the enhanced titanium line at 4444 was successfully adopted in conjunction with the cadmium line at 4455; the pair 4216, strontium, and 4250, iron, is available for all types of spectra from F to M; other pairs have a limited range of applicability.

In drawing curves connecting line-intensity with absolute magnitude, use was made of all the trigonometrical parallaxes deduced by recent methods, equal weight being given to all; $0·005''$ (in Mt. Wilson values $0·002''$) was added, as the reduction to absolute parallaxes. Some of the curves are reproduced in the Memoir. The catalogue contains no dwarf stars of types M or late K, as the spectra available from which to draw curves are too few.

All the 500 stars are in the Mt. Wilson spectroscopic catalogue, and its results are printed for comparison, the agreement being very satisfactory, especially in view of the complete independence of method of measurement. The parallax found for Arcturus is $0·145''$ as compared with $0·158''$ at Mt. Wilson, and $0·100''$ (trig.) at Yerkes; its absolute magnitude is 1·0; it therefore appears to be less remarkable for size and speed than was formerly thought. The brightest absolute magnitude in the catalogue is ϵ Geminorum, −1·5; the faintest are seven stars of mag. 6·0 and 6·1.

YERKES OBSERVATORY: TWENTY-FIFTH ANNIVERSARY.—The Yerkes Observatory celebrated its twenty-fifth anniversary last September; the address delivered on the occasion by the director, Prof. Edwin B. Frost, has recently been printed. He emphasises the paramount part played by Prof. G. E. Hale in its establishment. The spectroheliograph had recently been invented, and work with that instrument has been throughout a principal feature. The original spectrograph being inadequate for this work, part of the funds bequeathed by Miss C. W. Bruce were devoted to the spectroscope called after her, and more than 8000 stellar spectrograms have been obtained with it. These have already yielded many important results, though the information contained in them has not yet been fully investigated.

The 60-inch mirror was offered to Yerkes Observatory, but it was felt that it would have a wider field of usefulness at Mt. Wilson.

Visual work with the 40-inch refractor included Prof. Burnham's measures of double stars, and Prof. Barnard's work on clusters, nebulæ, comets, faint satellites, etc. It was also found that the instrument could be efficiently used for photography, by placing a yellow filter in front of the plate, which must be isochromatic. Successful photographs have been made of the moon, planets, nebulæ, and clusters; 6700 plates were taken for star-parallax. Allusion is made to Barnard's splendid series of photographs of comets, and the Milky Way; the Atlas of the latter is stated to be nearly ready for publication.

The total solar eclipses of 1900 and 1918 were observed by members of the staff, and arrangements are being made to observe that of next September in California. It is pleasant to learn that the observing conditions at Yerkes are probably the best that could be obtained within 500 miles of Chicago; the 40-inch instrument can be used for some 1700 hours per year.

The record of work is one of which the Observatory may well be proud.

Research Items.

THE QUIPU MYSTERY.—Twenty years ago the method of counting by the knotted Quipu was one of the mysteries of Peruvian archæology. Since that time several explorers have found them in use by shepherds in keeping account of their flocks. More modern Quipus are easily understood and can be used by any one. Prof. L. Leland Locke, to whom we are largely indebted for the solution of the problem, has now prepared for the American Museum of Natural History an elaborate, well-illustrated monograph in which all available evidence concerning the use of the Quipu as a means of counting has been carefully collected.

TATTOOING IN THE MARQUESAS.—In Bulletin No. i. of the Bernice P. Bishop Museum, Mr. W. G. Handy publishes an elaborate, well-illustrated monograph on tattooing in the Marquesas. The operation was extremely painful, and after each sitting local inflammation, followed by fever or swellings, persisted for a period of eight or ten days. The practice has now ceased, and the facts have been collected from an examination of about a hundred and twenty-five of the older generation. The designs, of which numerous illustrations are given, show much artistic taste. It cannot now be ascertained how far the practice possessed a magical significance, but in one case a woman seems to have been marked to protect her from evil spirits. But at the time of the cessation of the art it had become purely decorative.

STONE YOKES FROM MEXICO AND CENTRAL AMERICA.—Excavations in Mexico and Central America have disclosed certain objects of unusual and definite shape and of wide distribution, the function of which is unknown. The stone yoke is shaped like the letter U and is about two feet in height, with the bevelled outer surface often carved with elaborate designs. It has been impossible to identify these objects either in native manuscripts or in the many available examples of sculpture in stone and clay. The evidence now collected by Mr. S. K. Lothrop in the July issue of *Man* shows that the stone yoke was worn round the waist and that it served no utilitarian purpose. The suggestion now made is that the yoke may represent the underworld, because the outline resembles the Mexican symbol for that region, and also because the yoke is associated with death and sacrifice in the Santa Lucia sculptures. But the proof of this theory must await the presentation of new facts.

AIR SURVEY AND ARCHÆOLOGY.—Mr. O. G. S. Crawford has reprinted his paper on "Air Survey and Archæology," read before the Royal Geographical Society in March last. The main purpose of the paper was to distinguish by the aid of ground-plans and aerial photographs of camps like Cissbury and the Soldier's Ring near Martin, now in Hants, two varieties of the shelves and banks, known as lynchets. The first, or Celtic type, he attributes to the first wave of the Celtic-speaking peoples about 700 B.C., who introduced finger-tip pottery, new types of bronze implements, the use of iron, square camps, and the Celtic system of lynchets, boundary-ditches, and roads. The Saxon or "open-field" system was quite different from the Celtic type, and this is instructively illustrated by sketch maps of the Celtic and Saxon villages on Salisbury Plain. Mr. Crawford writes: "I find it difficult to express in suitable words my sense of the importance of air-photographs for archæological study. They provide a new instrument of research comparable only to that provided by excavation. They are second only to excavation in the results they will achieve. Their invention will prove as valuable to archæology as that of the telescope has proved to astronomy. They are not a substitute for field work, but they are the most powerful ally of the field archæologist."

THE PRESENT POSITION OF DARWINIAN THEORY.—In an article on this subject in the current number of *Science Progress*, Prof. E. W. MacBride first outlines Darwin's own position as developed in the first five chapters of the "Origin of Species." Among the points he emphasises are Darwin's belief that modifications due to use and disuse are inherited, and his view that acclimatisation and the inheritance of its effects must have played a part in evolution. After stating eight "laws" of Darwin, Prof. MacBride concludes that they are reducible to two: (1) the Lamarckian factor, (2) an indefinite tendency to vary to an unlimited extent in all directions. The second factor he discards after a discussion of mutations in several of their aspects. To reach this conclusion he relies upon the principle of regulatory balance, and states that the doctrine of the survival of the fittest implies that all the organs of an animal (or plant) shall be useful, meaning that the particular specific form or character of every organ must be useful. The article concludes with a discussion of recent evidence concerning the inheritance of acquired characters, a criticism of the age and area hypothesis, and a short reference to recapitulation.

BIO-CLIMATIC STUDY IN THE EGYPTIAN DESERT.—Bulletin No. 29 published by the Ministry of Agriculture, Egypt, gives a short discussion on the above by Mr. C. B. Williams, senior entomologist. The discussion is carried out to show that the statistics gathered by meteorologists relative to desert conditions greatly ignore the conditions for biological studies. The author, while approving of the Stevenson screen for meteorological purposes, suggests that there is a strange lack of Stevenson screens for sheltering purposes in the desert. An expedition was made for a week in August 1922, all the time that could be then spared, to get at the actual facts of local variation. The locality chosen was in the Wadi Digla, 12 miles south-east of Cairo and 7 miles in a direct line from the Nile. Observations were made at the camp on the south side of the wadi, mostly shaded from the sun; also just alongside the camp, on the rock, beneath a large piece of which was a cavity into which it was possible to crawl, and on a large flat-topped rock in the middle of the wadi, completely exposed, where black and white bulb thermometers *in vacuo* were observed. Other observations were made in a body of sand, in a burrow, in a bush, in a hole under stone, and in ant-lion pits. During the week the temperature of the surface sand showed a change from 17·5° to 58·2° C., while the air shade varied from 21·2° to 35·9° C., and twelve metres in a cave from 24·0° to 25·4° C. only. There was a great range of humidity and other conditions in the various positions.

COWS' MILK FOR HUMAN CONSUMPTION.—A conference on the milk question was held at the meeting of the Royal Society of Arts on April 25, of which an account is given in Journ. Roy. Soc. Arts, June 29. Prof. Stenhouse Williams maintained that it is not an impossible proposition to provide the public with a clean raw milk from cows which do not react to tuberculin, at a price which consumers ought to be, and are, willing to pay. Prof. Drummond, Dr. Zilva, and Capt. Golding dealt with the changes which take place in cows' milk on heating to various temperatures—

digestibility, influence on vitamins and enzymes—suggesting that it is inadvisable to employ heated, such as pasteurised, cows' milk for infant feeding. They seem to have overlooked the fact that cows' milk is not the natural food for the human infant, and that clinical evidence does not support the view that good fresh heated cows' milk is less satisfactory for infant feeding than the raw milk.

LANCASHIRE SEA-FISHERIES.—In his introduction to the report for 1922 on the Lancashire Sea-Fisheries Laboratory, Prof. James Johnstone has given an interesting summary, in non-technical language, of the present state of knowledge concerning the problems under investigation. Mr. Daniel's third and concluding paper on the seasonal changes in the chemical composition of the mussel (*Mytilus edulis*) deals with the distribution of fat and glycogen in the tissues, and he shows that it is the rôle of the connective tissue to store up these substances as reserve food-materials, afterwards to be used up by the rapidly growing sexual follicles during the time of preparation for reproduction. The study of the Irish Sea cod-fishery of 1921–23 by Messrs. Johnstone, Smith, and Fleming has led to the conclusion that there is no such definite seasonal variability in the metabolism of Manx cod as one finds in the herrings from the same district. Mr. Birtwistle and Miss Lewis conclude their report on scale investigations of shoaling herrings from the Irish Sea with a pertinent question :—" How are we going to reconcile these two positions, namely, that we can construct a curve from a sample of herrings which suggests that variations in length and scale rings are due to chance and do not indicate age, and at the same time we can construct a similar type of curve from a sample of plaice in which we do definitely know that the variations in length and otolith rings do indicate four different age groups ? "

LACE-WING FLIES.—Memoir 58 of the Cornell University Agricultural Experimental Station is devoted to an account of the biology of the Chrysopidæ written by Mr. Roger C. Smith. The insects included in this family are of particular interest in view of their predaceous habit of destroying various soft-bodied insects, etc., particularly Hemiptera. About sixty species of lace-wing flies are known in the United States, and the life-histories of eleven are described and illustrated with evident care. The general discussion of the family, which runs to about 50 pages, is particularly interesting, and should be read by all who study these insects. In discussing the function of the long pedicel, upon which each egg is laid, the author points out that it only affords partial protection from enemies. Only certain species of the larvæ carry debris on their backs and have specially modified setæ for retaining the material in position. The debris is used as a method of concealment, and consists of varied substances, including particles of plant tissues, exuviæ, and other insect remains. This material is placed by the larva on its back, but no silk is utilised in building it together. The larval food consists chiefly of eggs and small aphids and scale insects, but the larvæ are sometimes cannibalistic. It has also been observed that they frequently derive sustenance from plant tissues. The average number of aphids eaten by one of these insects during its larval life is about 170. Certain of the adult insects are also noted to devour aphids very readily. Chrysopids are subject to various insect enemies, and one of the most remarkable is a small blood-sucking midge, which attaches itself to the wings of the lace-wing and, burying its proboscis in a vein, sucks up the blood of its host.

JAPANESE TERTIARY FOSSILS.—Prof. M. Yokoyama, to whose valuable papers on the fossils of the Musashino beds we have previously directed attention (NATURE, August 26, 1920, p. 836, and November 11, 1922, p. 646), has now published a note " On some fossil Mollusca from the Neogene of Izumo " (*Japan. Journ. Geol. and Geogr.*, vol. ii. No. 1). The exact horizon of the beds is uncertain ; they are older than the Musashino formation, and if Pliocene should be referred to the Lower and not to the Upper division. Out of 19 species described, setting aside three as possibly obtained from beds not belonging quite to the same formation, there are seven species referable to existing forms and seven not known living which are here described as new. The relative proportion may, however, be modified on the acquisition of additional specimens.

THE GIGANTIC HORNLESS RHINOCEROS. — Prof. H. F. Osborn has followed up his scientific description of the skull of Baluchitherium, to which we referred recently (NATURE, July 14, p. 67), by a popular article on it and other rhinoceroses living and extinct (*Natural History*, vol. xxiii.). Well written and abundantly illustrated, this article is worthy of attention by more advanced students than those for whom it is obviously designed. So far as we are concerned the most interesting feature is the evolution of the idea as to Baluchitherium's size and form as expressed in three successive restorations. In the first it appears like an exaggerated rhinoceros with a proportionately slightly longer neck, while the last exhibits a slighter limbed, more upstanding animal, with elongate, horse-like neck, its height at the shoulder being increased in terms of a modern rhinoceros from 1·8 to 2·5. Its affinities to other rhinoceroses is yet in doubt ; but for its powerful superior tusks it would be considered as simply a giant Aceratherium.

OIL-SHALE FROM THE ROCKY MOUNTAINS.—Mr. D. E. Winchester has recently contributed a useful addition to the oil-shale literature of the United States Geological Survey in Bulletin 729, wherein he describes the well-known occurrences of the Rocky Mountain region. This volume is noteworthy because the author discusses an aspect of the subject usually slurred over by most writers, namely, the detailed fauna and flora of certain stratigraphical horizons to which the oil-shales are referable. The fauna includes a long list of insects (in the broad sense) and other arthropods of the Green River Formation (Eocene), while an abundant and varied flora has been described by Mr. F. H. Knowlton, the late Dr. C. A. Davis's contribution on the study of the micro-organisms being also incorporated in the text. The photomicrographs of thin sections of some of these oil-shales show an abundance of fossil vegetable-matter with which, presumably, the hydrocarbon content of the shale is connected. Some interesting data are recorded concerning methods of approximate evaluation of oil-shale in the field, the methods including simple retorting and test-tube experiments, the latter being especially useful. After all, even if there be millions of tons of shale-resources available for mining, the material is of little use unless it will yield oil in payable quantities. Hence field-tests, where definite, may save a great deal of unnecessary expense in initial development. This bulletin is profusely illustrated with photographs and maps, and a very complete oil-shale bibliography is appended ; it is, in fact, something more than a mere technical report, being a trustworthy handbook to the whole subject of oil-shale mining and exploitation.

WEATHER IN EGYPT.—The meteorological report for the year 1918 has recently been issued by the

Ministry of Public Works, Egypt. Daily observations are given for several elements at the principal stations, comprised by Helwan Observatory, which is the first-order station for Egypt, as well as Alexandria, Giza, and Khartoum. Monthly summaries are given for many other stations, and monthly rainfall results are added for several places. Weather conditions were generally unsettled from January to April and from October to December, but more settled weather was experienced from May to September. The temperature was much above the normal in the autumn months and about normal for the rest of the year, while atmospheric pressure was generally above the normal. Heavy rain of the thunderstorm type over Middle Egypt was a feature of the year. The Sudan rains were in considerable deficit. At Helwan, July was the hottest month of the year and the diurnal change of temperature was greatest; the mean temperature was 28·8° C., and at 5 A.M. the deficit of temperature was 6·7° C., while at 3 P.M. there was an excess of 6·7° C. The lowest mean temperature was 12·6° C. in January. The total rainfall for the year at Helwan was 36·7 mm. (1·45 in.), and no rain fell from June to September. Observations were commenced at Jerusalem in April 1918; the hottest month was July with a mean 22·8° C., while in December the mean was 10·0° C. No rain fell in June, July, and August; in December the total rain was 105·1 mm. (4·14 in.).

PECTIN IN COTTON.—Messrs. P. H. Clifford and R. G. Fargher have been examining the distillate from large-scale experiments upon the treatment of cotton with sodium hydroxide and superheated steam, conducted by the Bleachers' Association, Ltd. (Journal of the Textile Institute, vol. xiv. No. 5, May 1923). Methyl alcohol and acetone were the main volatile products isolated, a fact which supplies additional evidence for the presence of pectin in the cotton hair, as F. Tutin has shown (*Biochem. Journ.*, vol. 15, 1921) that the alkaline hydrolysis of pectin yields both these substances.

X-RAY INSTALLATION FOR VETERINARY WORK.—The Research Department, Woolwich, has published a description of an X-ray equipment, designed and constructed at Woolwich, which has been installed in the Army Veterinary School at Aldershot (R.D. Rep. No. 56). It consists of a large teak table-top to which the animal can be strapped while in the vertical position. The X-ray tube box is mounted on a carrier which enables it to be moved into any position relative to the animal, and the examination may be made or radiographs taken with the animal in the upright position. Alternatively, the table-top may be rotated and moved on rollers so as to bring the animal into the horizontal position over a supporting table. The X-ray tube used is of the standard Coolidge type, completely enclosed for protection in a lead box, and the generating set is designed to supply currents up to 20 milliamperes continuously at 150,000 volts. Full details of the apparatus are given.

INDUSTRIAL PSYCHOLOGY IN COAL MINING.—To attempt to teach a coal miner how to use a pick seems at first sight as valuable as taking coal from Dover to Newcastle; but a glance at two memoirs by Dr. C. S. Myers and Mr. E. Farmer in the June issue of the Memoirs and Proceedings of the Manchester Literary and Philosophical Society is sufficient to show how much is to be gained by investigating scientifically the best way of using such a tool. Mr. Adams and Mr. Stephenson, two post-graduate students of the Psychological Laboratory of the University of Manchester, have devoted twelve months of their time to the investigation, and have for much of this time lived the life and worked the hours of the miner. As a result, the wielding of the pick has been rendered more continuous and rhythmic and a greater output secured with less fatigue of the miner. The effects of improved lighting and more orderly arrangement of work so that less shovelling has to be done have also been investigated, and the miners themselves have taken a keen interest in the investigation.

A MERCURY FLASH-LIGHT FOR PHOTOGRAPHY.—In the Proceedings of the Physico-Mathematical Society of Japan for June there is reprinted a paper from the *Japanese Journal of Physics* by Kyoji Suyehiro on an "Electrically deflagrated Mercury Filament as a Flash-light for Instantaneous Photography." In investigations on the rolling of model ships and the vibration of structures, photographs of rapidly moving objects were desired. Prof. Anderson's experiments on electrically deflagrated wires as a source of light led to a trial of this method with fine tin and copper wires, but the results were not encouraging. Filaments of mercury were tried with success. Mercury is sucked up into a glass capillary tube, and in each end of the tube a "hair wire" is secured with sealing-wax. Thus filaments of any size are easily prepared. The duration of the flash is shorter as the filament is reduced in length and diameter, and it is also affected by the thickness of the wall of the tube. The most intense light is given out by the mercury arc lit just *after* the explosion. The paper is illustrated with photographs of flashes, results of testing their duration by means of a rotating disc with radial lines on it, and applications of the method.

MANUFACTURE OF WATER-GAS.—The Fuel Research Board of the Department of Scientific and Industrial Research has just issued, in its Technical Paper No. 6, a record of experiments at H.M. Fuel Research Station, Greenwich, on the "Comparison of some Methods of running Water-Gas Plant" (H.M.S.O., 2*s*. net). The manufacture of water-gas from coke is of great economic importance, and the accumulation of carefully ascertained data is correspondingly valuable. Observations were recorded on the behaviour of cokes of different origin when used in the generator (of the Humphreys and Glasgow pattern), and the paper deals also with four gasification tests with varying depths of fuel bed. The first three were made on the Dellwik-Fleischer system—with shallow beds of depth 3 ft. 6 in. to 4 ft. and varying rates of steaming. The fourth was made with a deeper bed on the system recommended by the makers. All tests were made on the same coke. The observations in the tests are given very fully in tables of weight and thermal balances, temperatures, and rates of gas production. The thermal efficiency of the generator was found to reach 59·9 per cent. in the Dellwik-Fleischer system and 57·8 per cent. under the normal regime, when no deduction was made for heat losses and expenditure in generating the power employed in the process. These deductions depend naturally on the efficiency of the auxiliary plant, and might depress the efficiency on certain conditions assumed, *e.g.* in the fourth test to 52·8 per cent. The greatest thermal loss occurred in the heat carried by the "blow gas" which lay in the four tests between 20 and 30 per cent. and sufficient theoretically to generate 80 to 130 lb. of steam per 1000 cu. ft. of water-gas made. This report may usefully be read in conjunction with the Sixth, Seventh, and Tenth Reports of the Gas Investigation Committee of the Institution of Gas Engineers published in 1921, 1922, and 1923, which give a more detailed study of the water-gas process in its various modifications, as operated in towns gasworks.

International Education.

"THERE is hardly any important national problem left in the world which has not an international relation and aspect." "The search for truth and its application to human need is a vast, world-wide co-operative task. . . . Every country should seek entangling alliances in a league for scientific progress." Of these quotations the first is from a speech made recently in London by Dr. Nicholas Murray Butler, the second from a report, published last year, by the president of the Rockefeller Foundation. Both indicate a point of view which has been adopted with enthusiasm since the War by a considerable number of people, especially in academic circles, in the United States. Both in America and on this side of the Atlantic, where it is more familiar, systematic efforts have been made to orientate higher education to some extent to this supra-national point of view.

In America two important organisations have been established expressly for the furtherance of International Education—the Institute of International Education by the Carnegie Endowment for International Peace, and the International Education Board by John D. Rockefeller, Jr. The Board, which only came into being this year and aims at promoting "education throughout the world," has made a grant of 100,000 dollars a year for ten years to Teachers College, Columbia University, to aid in establishing, as an integral part of the College, an International Institute for the instruction of foreign students (of whom there are already some 250 in the College) and of Americans engaged in teaching in foreign countries, and for research and investigation into foreign educational conditions and the adaptation to those conditions of American systems and methods of education. The Board aims at establishing mutually helpful relations with other countries in regard to selected specific educational problems, and has already arranged for a study of co-operative farming methods in Denmark. Many of the activities of the Rockefeller Foundation, with which the Board is closely associated, have an international educational character: of the 157 individuals who held the Foundation's fellowships in 1921 only 71 were Americans, the others belonging to 17 other nationalities.

The Institute of International Education began work in 1919, and its director, Dr. S. P. Duggan, has recently presented its fourth annual report. Among its varied achievements during 1922 was an agreement with the Commissioner of Immigration at Ellis Island, designed to mitigate in its application to students the new American immigration law limiting to specified quota the number of immigrants from foreign countries, the director undertaking to act as sponsor for properly certificated students and the commissioner agreeing to admit such students provisionally on parole. Among its other enterprises may be mentioned: arranging for the selection and distribution of 45 fellowship-holders from France for study in the United States and 35 from the United States for study in France; acting as agent for the Spanish Junta para Ampliación de Estudios, which sent 6 fellowship holders to the United States, and for the Czechoslovakian Government, which sent 5; assisting the French authorities to select French girls for training, partly in France and partly in America, in library work and public health nursing; securing fellowships in American institutions for foreign students; promoting resort by Americans to summer sessions in foreign universities; organising student tours in Italy, France, England, and Scandinavia; arranging exchanges of professors; and promoting the formation of International Relations Clubs for the discussion of international questions. The Institute has now an established place as one of the most influential of existing organs for the development of intellectual intercourse among the nations of the world.

In Great Britain the most important single endowment of international education is that provided by the Rhodes Scholarship Trust. Provision is now made under the trust for the continuous residence at Oxford of 190 scholars selected from English-speaking countries outside the United Kingdom. A peculiarity of the method of selection for these scholarships is an insistence on moral force of character, capacity for leadership; in short, all-round ability, as well as literary and scholastic attainments. A similar principle is prescribed for selecting candidates for the 6 Henry P. Davison scholarships founded this year to provide for Oxford and Cambridge men spending a year at Harvard, Princeton, or Yale. A few scholarships similarly designed to draw students from abroad are offered by certain Cambridge Colleges, the Imperial College, and the universities of Liverpool, Manchester, McGill, Harvard, Princeton, and Yale, most of them being open only to students of countries within the British Empire.

Conversely, many universities have endowments, such as the Craven Fund and Radcliffe travelling fellowships fund, which encourage students to go abroad for study or research, generally in some specified field, such as modern languages and institutions, classical studies, or the fine arts, in which sufficient facilities are not available at home. Similarly various governments and voluntary associations, such as the federations of university women, the Anglo-Swedish Society, and the Canadian Imperial Order Daughters of the Empire, have instituted scholarships enabling students to travel to distant countries for educational purposes. The Government of Panama, for example, periodically sends two carefully selected students to universities in Great Britain for complete degree courses of study. The Albert Kahn travelling fellowships, open to British graduates of universities of the United Kingdom, are remarkable for their breadth of aim—"to enable men . . . to enter into personal contact with men and countries they might otherwise never have known; to issue from the world of books . . . into the broader world of . . . all such human interests, struggles, and endeavours as go to the making up of general civilisation."

Apart from endowments for encouraging international education by scholarships and fellowships there are many influences, some of quite recent origin, having a similar tendency. The universities of the United Kingdom have instituted a new doctorate, the Ph.D., open to graduates of foreign universities as well as to their own, and have organised in connexion therewith instruction in research methods; their laboratories and other equipment for advanced study and research have been greatly developed; their representatives have taken part in missions to American, French, Belgian, and Swiss universities; they have established a standing committee of their executive heads with the Universities Bureau as its secretariat, and a separate committee for promoting interchange of students and teachers with universities in other lands—a purpose which has been greatly furthered by the constitution of the British divisions of the American University Union and the Office National des Universités et Écoles Françaises, both of which have offices in the house belonging to the Universities Bureau. There

has also been a notable development of short summer-vacation courses (mainly in London) for foreign students as well as of other summer courses, to which, although not planned expressly for them, foreigners are admitted. Interchange of school teachers (for periods not exceeding one year) between England and Wales and the Dominions overseas has been organised by the League of the Empire on a large scale, and other bodies such as the Overseas Educational League and the Fellowship of the Maple Leaf, are engaged in similar enterprises.

Several European countries participate in exchanges financed by American educational endowments. The Commission for Relief in Belgium Educational Foundation of New York arranges, in concert with the Fondation Universitaire of Brussels, grants for study in American Universities to Belgian graduates and vice versa (in 1921–22, 34 and 24 respectively). The American-Scandinavian Foundation similarly allots 40 travelling fellowships, each of 1000 dollars, and the Franco-American Scholarship Exchange, administered by the American Council on Education, provides 50 scholarships for French women in American colleges, 28 for American women in French lycées and écoles normales, and 22 fellowships for American graduates in French universities.

In France the Doctorat d'Etat has been made more accessible to foreign graduates, a system of exchanges of professors has been arranged with certain American universities, and the summer-vacation courses for foreign students in vogue before the War have been re-established and extended. In 1919 a Franco-Swiss interuniversity conference took place, and in 1921 a convention was concluded, between the French and Belgian ministries of public instruction, to encourage and regulate the exchange of professors and students and to establish a permanent technical commission for the study of questions regarding the scientific, literary, artistic, and scholastic relations between the two countries.

In the same year, 1921, were formed the Netherlands Committee for International Academic Relations and the Office Central Universitaire Suisse.

The Confédération Internationale des Étudiants, formed in 1919, has contributed substantially in co-operation with its affiliated national unions, towards familiarising students with the idea of migration. The National Union of Students of England and Wales, constituted in 1922, has been very active in promoting visits by students to universities in foreign countries.

In the nineteenth century one of the most powerful influences making for migration of students was the great reputation of the German universities for profound learning and for primacy in scientific research, together with their liberal conditions of entrance. In the United States especially a German doctorate came to be looked upon as a normal culmination of the studies of an ambitious youth. The tradition was fostered by the system of exchange of professors arranged by the Prussian ministry of education with American universities. Before the War, however, a reaction had set in, due in part to the rapid development of the American graduate schools.

The League of Nations decided last year to enter the field of International Education, and a Committee on Intellectual Co-operation, having a sub-committee on Interuniversity Relations, is actively engaged in devising ways and means of stimulating movements and enterprises such as those mentioned in this article, including the establishment of an international bureau of university information.

The question of interchange of students has an economic aspect which deserves study. At the present time students from abroad constitute about eight per cent. of the full-time students in the universities and university colleges of the United Kingdom. Statistics showing the number of students from the United Kingdom in universities and colleges in all other countries are not available, but those in the United States in 1920–21 numbered 181, and those in other parts of the world are certainly very few compared with the total of more than four thousand students from abroad in the British Isles. Is the fact that our imports so largely exceed our exports to be accounted economically advantageous to us or the reverse? The fees paid by students represent, of course, only a fraction of the costs of maintenance of the institutions where they study, and in universities such as Oxford, Cambridge, London, and Edinburgh, which are frequented by students from abroad in large numbers, the additional expenditure necessitated by their attendance is probably not compensated by their fees; but there is a more important question in regard to the students who come to Great Britain to study technology. When they go back to their own countries they take with them knowledge which is used so as to make the competition of their countries' industries with our own more formidable. On the other hand, they are likely to recommend the placing of orders for stores and machinery in the country in which they have studied rather than in other countries, and if they had not come to Great Britain for their knowledge they would probably have obtained something very like it elsewhere. It may be that such students do British industries more good than harm. The matter is one on which it is desirable that further light should be, if possible, obtained.

Botanical Surveys.

THE Department of Agriculture of South Africa has recently issued two memoirs (Nos. 3 and 4) on the botanical survey of South Africa. The former, by S. Schonland, entitled "Introduction to South African Cyperaceæ," is a systematic account of a selection of the indigenous sedges, many of which play an important part in the prevention and cure of soil erosion, and a knowledge of which is essential in the study of the relations of sour and sweet veld. A description of the general structure of the vegetative organs, the inflorescence, the difficulties in the interpretation of which are discussed in some detail, the flower and the fruit, is followed by notes on all the South African genera, including representative species of each. The species are illustrated by seventy carefully drawn plates, which show the habit of the plant and enlarged details of flower and fruit, and will enable the student to identify any species included in the limits of the book. The general arrangement is the one adopted in the "Flora Capensis" by the late Mr. C. B. Clarke, to the thoroughness of whose work Dr. Schonland pays high tribute. The critical remarks included in the notes on the genera render the work of value to others than the South African student of this family.

Memoir No. 4, entitled "A Guide to Botanical Survey Work," is a series of chapters, by different experts, which will be helpful to those engaged in the South African survey. Dr. Pole Evans reiterates the organisation and aims of the survey, and describes briefly the characteristics of the two main botanical regions, the true Cape region, with a vegetation resembling in its general aspect that of the Mediterranean area, and the South African region, which

comprises the remainder of the country under review, extending northwards to include a strip of Southern Rhodesia and the southern part of Portuguese East Africa. There are also chapters on the physical features and climate, on methods of survey, with instructions to collectors and observers, and a bibliography. Dr. Marloth writes on the use of the common names of plants, which, though sometimes not trustworthy, may be very useful if accepted with care and discretion.

The Report of the Canadian Arctic Expedition 1913–18 (vol. v., Botany, part B) by Theo. Holm ("Contributions to the Morphology, Synonymy, and Geographical Distribution of Arctic Plants") contains some interesting notes on the methods of growth and reproduction, manner of hibernation and other characteristics, of many of the species collected by the expedition. Certain biological types are absent from the polar regions; there are no climbers, no saprophytes, and no true parasites. Pedicularis alone represents the partial parasites. The great majority of the herbs are perennial. The chapter on geographical distribution contains a table showing the general distribution of the species collected, which indicates that the vegetation of the north coast of America is composed of types from various parts of the northern hemisphere of both worlds, and bears out the view that the present arctic flora consists to a great extent of remnants of the alpine floras of the tertiary period. These alpine floras were principally those of the European Alps, Altai and Baikal, the Rocky Mountains, and perhaps also Caucasus and Scandinavia.

Memoir 126, issued by the Canadian Department of Mines ("A Botanical Exploration of the North Shore of the Gulf of St. Lawrence," by Harold St. John), includes an annotated list of all the flowering plants and ferns recorded from this area, in all 622 species, and some discussion of the soil-relations of the various ecological plant groups. A comparison of the habitats of 103 species along the north shore of the gulf and in other regions, especially Europe, indicates an agreement the more surprising considering that the data have been gathered by many botanists at widely separated places and times. Mr. St. John also gives an account of botanical exploration in the same area previous to his own visit in 1915.

"A Flora of the Shetlands," by Dr. G. C. Druce, forms a supplement to the recently issued report of the Botanical Society and Exchange Club for 1921. The total land surface of the islands, which number more than a hundred, is rather more than that of the Faroes, but the hills are lower and lack the marked alpine element found in the flora of the Faroes. The population of the islands since the glacial period has been explained alternatively by the existence of a land-bridge and immigration by means of birds, ocean-currents, and wind. The latter view would seem the more probable. There are practically no endemic species, and many species found in the islands are extremely local. The flowering plants and ferns number about 500 species, 59 of which have probably been introduced by man. Dr. Druce remarks on the size and brilliancy of some of the flowers, and suggests the feeble intensity of sunlight as a cause; clouds are absent from the sky only on a few days in the year, and mists are very frequent. There are few Lepidoptera; many plants are self-pollinated, and others never ripen seed. The flora approximates most closely to that of the Faroes, and is distinctly poorer than that of the Orkneys.

The Gas Industry and Coal Conservation.

THE annual coal output of Great Britain is about 300 million tons, of which approximately 20 million tons are carbonised annually in gasworks for the production of towns' gas. The reserves of British coal within 4000 feet of the surface were estimated in 1915 at 197,000 million tons. In something like 600 years the coal measures of this country will be probably exhausted, and what then? The world's scramble for oil to-day indicates that a coal age will certainly not be succeeded by an oil age. Possibly we shall have learnt to tap atomic sources of energy, or perhaps the earth's internal heat may be available to us, after the manner suggested by Sir Charles Parsons.

There are those who hold that how posterity will provide itself with supplies of energy is posterity's own concern and need cause us no uneasiness; the gas industry takes a wider view. Its processes are continually being examined with a view to effecting greater conservation of coal. In a Report to the Institution of Gas Engineers in 1919, by Sir Dugald Clerk, Profs. Cobb and Smithells, it is shown that the thermal efficiency of the process of carbonisation of coal achieved to-day in the United Kingdom is from 70 to 80 per cent., and that debiting gas with the whole of the thermal losses of the process and allowing for transmission and other losses, at least 45 per cent. of the heat of the coal carbonised is delivered to the consumer as inflammable gas. This is a high figure, but it can be considerably improved upon if the heat content of the coke produced, amounting to more than 10 cwt. per ton of coal carbonised, is made available to the consumer by the conversion of the coke into gas. The Gas Regulation Act, 1920, had this point among others in view when it conferred upon individual gas undertakings freedom to declare the calorific value of the gas each would supply. As there appears to be considerable confusion of thought on this matter, perhaps it were as well if we explained briefly the nature of the component mixtures constituting towns' gas.

> "We see all sights from Pole to Pole,
> And glance and nod and bustle by,
> And never once possess our soul,
> Before we die."

Blue water gas is produced from coke by passing air and steam alternately over an incandescent bed of this fuel. Its calorific value is about 300 B.Th.U. per cubic foot, and its composition is approximately represented by CO_2, 4·5 per cent.; CO, 43 per cent.; H_2, 48 per cent.; methane, 0·5 per cent., and nitrogen, 4 per cent. Sometimes this gas is mixed direct with coal gas in a towns' gas supply, a customary proportion being 80 per cent. of coal gas and 20 per cent. of water gas, the percentage of carbon monoxide in the resulting mixture being approximately 14 per cent. and the resulting calorific value about 500 B.Th.U. per cubic foot. More commonly, however, carburetted water gas, produced by enriching blue water gas with gaseous hydrocarbons derived by "cracking" various oils at high temperatures, is used for this purpose. The carbon monoxide content of carburetted water gas is on the average about 27 per cent., and, when admixed to the extent of about 20 per cent. with straight coal gas, a mixture containing approximately 11 per cent of carbon monoxide results. Straight coal gas produced by the high temperature distillation of coal has a calorific value of about 560 B.Th.U. per cubic foot and contains about 7 per cent. of carbon monoxide.

The thermal and chemical efficiencies of manufacture of different grades of gas by various processes have been the subject of three reports by a Joint Committee of the University of Leeds and the Institution of Gas Engineers. The first Report dealt with the process of steaming the charge in continuous vertical retorts, and the results showed that the thermal efficiency of gas production increased from 54·5 per cent. without steam to a maximum of 62·1 per cent. with moderate steaming, and at the same time increased yields of tar and ammonia were obtained. These results were later confirmed by work carried out about the same time by the Fuel Research Board. The second Report showed that the efficiency of production of blue water gas as ordinarily practised in a plant without waste heat boilers, taking into account the steam required for the operation of the plant, averaged 46 per cent. In the third Report on the subject (contained in the Committee's Seventh Report, a copy of which has just been received, presented to the Institution of Gas Engineers in June 1922), the Committee shows that the percentage thermal efficiency of production of carburetted water gas of calorific value about 485 B.Th.U. per cubic foot, taking into account all steam required, was increased from 59·5 per cent to 68 per cent., by the use of waste heat boilers employed for steam raising by means of waste heat in the flue gases. The efficiency of production of blue water gas was 53 per cent. and of the production of gas from oil for carburetting 90 per cent. The percentage thermal efficiency of the waste heat boilers averaged only about 46 per cent.

The problem foremost in the mind of the gas industry to-day is the production and distribution of the Therm at the cheapest price. The maximum conservation of coal within the industry will be achieved when that problem has been settled. While the Fuel Research Board could not, from the nature of the problem, specify any one grade of towns' gas as being under all conditions most suitable for production and distribution, its recommendations, embodied in the Gas Regulation Act, 1920, do, for the first time in the history of the industry, enable the relative efficiencies of gas production by various processes and in different parts of the kingdom to be compared on a scientific basis. The work of the Committee to which reference is here made is evidence of the quickened interest on the part of the gas industry in these matters and an earnest of higher efficiencies yet to be realised, and a cheaper Therm still to be distributed.

J. S. G. T.

Optical Works of Messrs. Adam Hilger, Ltd.

THE show-rooms of Messrs. Adam Hilger, Ltd., 75A Camden Road, London, N.W.1, contain a very interesting exhibition of optical instruments, to the inspection of which visitors are cordially invited. A short account of some of the devices and operations seen during a recent visit to the works may be of interest to readers of NATURE.

In a room devoted to the grinding and polishing of lenses and mirrors, a recently silvered mirror was being coated with a thin varnish to preserve the surface of the film which was not in contact with the glass, and was to be used to reflect light in an optical instrument in the same way that a silvered mirror is used in an astronomical telescope. The mirror was circular and about 4 inches in diameter, cathodically silvered. It was mounted by soft wax on a wooden mandril which revolved on a vertical shaft at some thousand revolutions per minute with its silvered surface uppermost. Dust was brushed from the surface by means of a fine camel's hair brush, and then a weak solution of celluloid in amyl acetate was poured upon it and left to dry, while the mirror was rapidly revolving. This left a thin film of celluloid on the mirror, which preserves its brightness. Films which are thick compared with a wave-length of light protect the silvered surface almost indefinitely, but these do not allow of the highest definition. On the other hand, films which are thin compared with a wave-length of light do not preserve the silver so well, but do not, however, in any way adversely affect the optical performance of the mirror. Films of intermediate thickness would tend to produce colours on the principle of Newton's rings.

Several prisms of rock salt were seen in process of manufacture; these cannot be ground with water as in the case of glass, owing to its dissolving action on the substance, so paraffin is used instead, and the accuracy of the rough grinding is tested by steel sets of 60° angle. All finished optical surfaces are, of course, tested by interference methods, the source of light being the mercury vapour arc. A Lummer plate was being tested by this means. Newton's rings were used, and they were plainly visible in spite of the thickness of the plate.

In another room the thickness of a piece of plain parallel quartz some $1\frac{1}{4}$ in. × $1\frac{1}{4}$ in. × $\frac{1}{8}$ in. was being measured on a Michelson interferometer. The half-coating of silver had been removed from one of the mirrors of the instrument, and the specimen was then "contacted on" to this mirror so as to cover one half of it. The whole was then half silvered, and the distance between the two surfaces was measured in air. What appeared to be a slight scratch in the centre of the specimen was in reality a slit in the glass, of width only 16 wave-lengths of light (λ5461). This slit was made in the manner illustrated in the accompanying diagram (Fig. 1). It will be seen that the quartz plate was in reality built up of four pieces, all optically finished with extreme accuracy. Starting with 1, 2 and 3 were contacted on and heated sufficiently to make these three join up into one piece, but, of course, not too much, or the optical perfection of the surfaces would be spoilt. The protruding edges of 2 and 3 where they meet 4 were then ground and polished so that they extended beyond 1 a distance equal only to 16 wave-lengths. This distance was measured with the Michelson interferometer, and then 4 was contacted on and the heating process repeated.

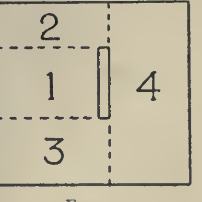

FIG. 1.

In the workshops an accurate screw was being cut similar to that which is used in the Fabry and Perot interferometer. This was done on an automatic electrically controlled lathe. Whenever the cutting tool reached the end of its stroke, electrical contacts were made, which moved the tool away and brought it back to the beginning of the next cut. The screw, when turned, is rotated from end to end through a long split nut, driven by an electric motor with an automatic reversing gear. The nut contains a thermometer, the temperature of which is read from time to time to avoid over-heating, and this is apparently sufficient for the purpose, though one might have thought that an oil-bath would have kept the temperature more constant. Great care has to be

taken with the end thrust bearing of this screw, so that no periodic error may occur when it is in the instrument. To ensure this, the end of the screw has a small flat surface optically ground and polished. This rests against a ruby plate to take the end thrust of the screw. The plate is capable of adjustment, and there will be no periodic error when the system of interference fringes which can be observed between the ruby plate and the end of the screw remain unchanged while the screw is revolved. The screw is said to be true to 1/100,000 mm.

Among other things seen were the testing of a camera lens for non-axial rays by the interference method recently perfected by Mr. Twyman, and fully described by him in one of the catalogues and elsewhere,[1] and some extremely delicate thermo-junctions for spectro-bolometric work.

Mr. Twyman states that the large majority of those who come to inspect Hilger's showrooms, or apply to be shown over the works, are foreigners, and it is with the hope of bringing this exhibition to the knowledge of British men and women who are interested in optical design and spectrographic work in general, that the foregoing has been written.

C. C. L. GREGORY.

1 "An Interferometer for testing Camera Lenses." Read before the Optical Society, April 14, 1921

Biometry and Mathematical Statistics.

IN the new double number of *Biometrika* (vol. 14, Parts 3 and 4, Cambridge University Press. Price 30s. net) ample evidence is provided to show how groundless is the charge that the interest of modern statistical work is wholly mathematical. Of the ten memoirs published, only three require for their intelligent perusal more than a very moderate knowledge of algebra. The three mainly mathematical papers are Mr. Egon Pearson's evaluation of the probable error of a Class-index correlation, Prof. Pearson and Miss Elderton's paper on the Variate-difference method of determining correlation —a valuable contribution to the controversy which has arisen over the applicability of this method to various kinds of data—and Mr. E. C. Rhodes' paper on a particular type of Skew Correlation surface.

The most important of the biometric papers is Mr. Morant's careful study of the Tibetan skull. Mr. Morant concludes that there are in Tibet at least two distinct races—one closely allied to the Southern Chinese, Malayans, and Burmese, the other not showing any close affinity to any other oriental race, but resembling most the Burmese B and C types. He conjectures that he may here be dealing with widely scattered fragments of a fundamental primitive human type, with a long-headed, broad-faced, rugous and massive cranium.

Dr. Lucy Cripps, Dr. Major Greenwood, and Miss E. M. Newbold contribute a study of the inter-relations of "vital capacity," stature, stem length, and weight, based upon data furnished by the medical department of the Royal Air Force. They conclude that, so far as these data are concerned, Prof. Dreyer's modifications of Hutchinson's methods, in particular the substitution of stem length for height, are not marked improvements. Miss Elderton's memoir on the present position with regard to the inheritance of intelligence concludes with the words: "To each of us a limit is set, a limit, as far as one can see at present, due to heredity rather than to opportunity, and to the intelligence of our parents and ancestors rather than to the educational system under which we were reared."

Dr. Percy Stocks describes—giving a pedigree—a facial spasm inherited through four generations. Two other papers—one a short addendum to a memoir on the sesamoids of the knee-joint, the other on a digital anomaly—are of medical interest. Dr. G. D. Maynard discusses the fertility statistics of the New Zealand census. The *miscellanea* contain two notes on points of method and reviews of two recent contributions to mathematical statistics.

There must be very few students of pure or applied statistics who will fail to find anything of interest to them in this issue of *Biometrika*.

Glacial Deposits and Palæolithic Cultures in East Anglia.

AT a meeting of the Royal Anthropological Institute held on June 19, Mr. H. J. E. Peake in the chair, Prof. P. G. H. Boswell and Mr. J. Reid Moir presented a paper on "Flint Implements at Foxhall Road, Ipswich." Prof. P. G. H. Boswell dealt with the geology of the deposits. The site lies in an oval hollow about 120 ft. above Ordnance datum, 1¼ miles E.N.E. of Ipswich station. The surrounding plateau of glacial sand and gravel lies at about 130 to 140 ft. above Ordnance datum. The succession of general sequence of deposits from bottom to top down to a depth of 31 ft. 4 in. is as follows: Dark Chalky-Kimmeridgic Boulder Clay (bored to 2 ft. 6 in.), loamy sand and shingle (6 ft. 9 in.), sandy boulder clay and loam (3 ft.), gravelly and sandy brick-earths passing up into laminated brick-earths (15 ft. 3 in.), gravel and subsoils, etc. (3 ft. 10 in.). Mechanical analyses of the respective beds have been made, and as a result suggestions were offered regarding conditions of deposition. The mineralogical characters have also been worked out, the assemblage being of typically glacial character. Reasons for referring the lowermost deposits to the Chalky-Kimmeridgic Boulder Clay were given, and the evidence that the uppermost gravel indicated a recrudescence of cold or even glacial conditions after a period of amelioration were discussed. Finally, tentative correlations with the glacial sequence in Lincolnshire and Yorkshire were attempted.

Mr. J. Reid Moir described the implements found in the excavations. The number of humanly-flaked flints totals 545: the latest artefacts in Beds Nos. 2 and 3 being referable to the Mousterian epoch; the unrolled hand-axes of Beds Nos. 4 to 6 are of late Acheulean date; while those recovered from Bed No. 7 appear to represent examples of early Acheulean workmanship. Associated with the well-finished implements in the beds mentioned were found a number of simply-made artefacts, such as scrapers, points, and borers. Burnt flints were also recovered from each implementiferous horizon; while quartzite hammer-stones occurred in Bed No. 7. With the exception of one small and unidentifiable piece of bone, no organic remains were found during the excavations. An examination of the artefacts recovered shows that the specimens were flaked differently at the different horizons mentioned, and that a large proportion of the flints are considerably striated; the pressure to which

the specimens have been subjected has not, so far as can be seen, resulted in the removal of flakes. Several rostro-carinates—representing partly finished hand-axes—were found in the Acheulean strata.

In the discussion which followed the paper, Prof. W. J. Sollas said that we now have convincing evidence that the greater part of the Mousterian was glacial, and late glacial—Würm—at that. It is possible that the earlier Mousterian implements of the type of La Micoque belong to the interglacial Riss-Würm. The Upper Acheulean implements found at the top of the lower loess must therefore be referred to the Riss glaciation. There are difficulties, however, and while it might be expected that something intervened between Acheulean and Mousterian, there is no evidence that anything did. Mr. Bury pointed out that while on this site there is a separation between Chelles and Acheulean types, such separation does not occur in the gravels south of the Thames. Curiously, the site also shows a gradual climatic change working up from Acheulean to Mousterian, while south of the Thames the implements occur at different levels—the Acheulean at 100 to 150 ft., and the Mousterian, if occurring in gravels at all, at lower levels. It was this apparently to which Prof. Sollas referred.

Mr. Peake said that this investigation appears to clear up the difference between monoglacialists and polyglacialists. One point, however, has not been cleared up, and that is the relative position of the different industries. On the Continent it is generally held that the Mousterian equated with the Würm, but in America Prof. Osborne at least appears to have abandoned this position. The question arises, which of the four glaciations recognised on the Continent equate with the three glaciations for which there is evidence here? Prof. Boule has maintained that he is unable to find marked evidence for the Gunz glaciation in Western France. This suggests that the centre of glaciation was farther east, and that similar conditions prevailed in this country. In this case our three glaciations would equate with the three later of the Continental glaciations.

University and Educational Intelligence.

LEEDS.—One of the most important departments of the University is that which deals with agriculture, for, while the University is situated in a great industrial city, it is also the centre of the largest agricultural county in England. A new building for the department is about to be commenced. This has been made possible by the generous help received by the University from several sources. The late Mr. Walter Morrison gave a sum of 10,000*l*., a donation which, by his wish, remained anonymous during his lifetime; a Treasury grant through the Ministry of Agriculture and Fisheries of 12,000*l*., promised in 1914, has been increased to 15,000*l*.; the Yorkshire Council for Agricultural Education has contributed approximately 10,000*l*.; and there have been numerous other donations. The University is providing the site and the balance of the money required. The building will be located in University Road, west of the buildings of the Textile (Clothworkers) group, and will occupy a plot 190 feet long by 125 feet deep.

LONDON.—The following doctorates have been awarded, the subject of the thesis presented appearing after the name:

Ph.D. (*Science*):—H. E. M. Barlow (University College): "An Investigation of the Friction between Sliding Surfaces, with special reference to the Effects produced by Electric Currents passing across such Surfaces"; Miss F. E. Barnett (Northern Polytechnic Institute): "Some Problems of the Endodermis—The Distribution of the Endodermis in Angiosperms, with some Observations on the Function of the Endodermis"; W. A. P. Challenor (Imperial College, Royal College of Science): "Conditions underlying Carbon Ring Formation"; B. W. Clack (Birkbeck College): "A Research on Diffusion in Liquids"; P. W. Cunliffe (King's College): "(*a*) Studies in Photo-Chemical Light Sources; (*b*) Studies on the Photolysis of Aqueous Solutions of Hypochlorous Acid and of Chlorine"; F. Dickens (Imperial College, Royal College of Science): "The Conditions of Formation of Four- and Five-membered Rings from Substituted and Unsubstituted Open Carbon Chains"; Miss C. H. Griffiths (Birkbeck College): "(1) Diffraction Patterns in the presence of Spherical Aberration; (2) Co-efficients of Diffusion of Potassium Chloride, Sodium Chloride, and Potassium Nitrate determined from the published experimental data of Mr. B. W. Clack by a method due to Dr. Albert Griffiths"; A. A. S. El Kirdany (Imperial College, Royal College of Science): "The Calculation of the Motion of an Inviscid Fluid round an Aerofoil when Cyclicity is assumed to be present"; Miss I. E. Knaggs (Imperial College, Royal College of Science): "The Relation between the Crystal Structure and Constitution of Carbon Compounds, with special reference to simple Substitution Products of Methane"; K. C. Pandya (Imperial College, Royal College of Science): "The Influence of Groups on Cärbon Valency Direction"; H. A. Piggott (Imperial College, Royal College of Science): "A Study of the Conditions which determine the Mobility (or otherwise) of certain Potential Tautomeric Systems of the Glutaconic Acid Type in the Aromatic Series"; H. H. Potter (King's College): "Some Experiments on the Proportionality of Mass and Weight"; L. Rebekoff (King's College): "(*a*) Studies in the Photolyses of Formic and Oxalic Acids; (*b*) Studies in some Photochemical Light Sources"; D. O. Shiels (King's College): "The Adsorption of Water Vapour and other Vapours by Charcoal"; B. Singh (Imperial College, Royal College of Science): "Formation and Stability of Cyclic Compounds derived from B Substituted Glutaric Acid"; I. W. Wark (University College): "Some Copper Complexes with Hydroxy-Acids"; A. F. A. Young (King's College): "The Thermionic and Photo-Electric Properties of the Electro-positive Metals"; F. Arnall (Chelsea Polytechnic): "Studies in the Nitration of Phenol"; G. R. Clemo (Queen's College, Oxford): "The Introduction of the B-chloro-ethyl Group into Phenols, Thio-phenols, Aromatic Amines, etc."; J. W. Cook (Sir John Cass Technical Institute): "Some Derivatives of Anthracene"; B. S. Evans: "An Investigation into the Chemistry of the Reinsch Test for Arsenic and Antimony, and its Extension to Bismuth"; P. T. Freeman: "On the Binaural Location of a Source of Sound of Low Frequency, and its Application"; S. I. Levy: (1) "Studies on Cyclic Ketones, Parts II. and III."; (2) "An Attempt to resolve an Oxonium Salt"; (3) "The Action of Amino-Acid Esters on Ethyl Dicarboxyglutaconate"; (4) "(4'-Methoxy-1'-naphthyl)-2-chromon"; A. H. Stuart: "The Problem of securing Rigidity in an Aeroplane Wing"; and C. L. Withycombe (Imperial College, Royal College of Science): "Neuroptera, their Biology and Anatomy."

APPLICATIONS are invited for the Drapers' Company's research scholarship in dyeing at the Technical College, Huddersfield. The scholarship includes re-

mission of fees, together with a maintenance grant of 100*l*. per year. Further particulars and forms of application may be obtained from the Secretary of the College.

A REPORT on "Health for School Children" prepared by the National Child Health Council's advisory committee on health education has been published by the United States Bureau of Education as School Health Studies No. 1. Its keynote is given in the following words: "It is essential that health shall not be regarded as an isolated subject. . . . Health motives and practices should permeate the whole school life and work. Methods of teaching health, of illustrating health, and of living health cannot be torn out or set apart from the child's life, but should be woven into its very fabric." It follows that all elementary-school teachers must be indoctrinated with proper health ideals and principles and inspired with an active appreciation of their importance; and likewise that the active co-operation of parents must be sought. Normal schools must give all students a grounding in general science (chemistry, physiology, bacteriology, and biology), personal hygiene, community and social hygiene, and nutrition, including fundamental instruction regarding foods and normal growth; but even more essential than instruction in these subjects is attention to the health of the students themselves, for "better far a young teacher thoroughly well and with some enthusiasm for health and no methods, than one who is even a little neurotic, a trifle hollow-chested, but method-perfect." In summer sessions normal schools should make health courses obligatory. The committee is considering the publication of a bibliography.

"PHILANTHROPY in the history of American higher education" is the subject of a bulletin (1922, No. 26) of the United States Bureau of Education prepared by Prof. Sears, of Stanford University, California. The writer, summing up the results of his researches, observes that although the "dead hand" may be said to rest in some degree upon most of the institutions of higher education, their vitality is not appreciably affected thereby. This is attributed partly to colleges and universities refusing gifts to which undesirable conditions are attached, and partly to the good sense generally evinced by benefactors. A description is given of a new type of foundation which is said to be coming rapidly into favour. It combines some of the characteristics of a joint-stock company with those of a public trustee. The Cleveland Foundation, the first of this type, has for its object "the mental, moral, and physical improvement of the inhabitants of the city." It receives gifts and bequests, however small, and whether accompanied by any expression of wishes as to their disposition or not, but undertakes to respect such wishes only in so far as shall seem to the board of directors wise and beneficial. The members of the administrative committee are appointed partly by the mayor, the judge of the probate court, and the federal district judge, and partly by the trustee company which manages the principal as a single trust. Prof. Sears does not allude to the injurious effects on college administration of the habit of looking to philanthropists for gifts, yet it is notorious that college presidents have sometimes been chosen mainly on the ground of their supposed efficiency as soliciting agents; nor does he mention the all-important consequence of so-called benefactions—that they must, in the end, to use the words of another writer on this subject, "involve a personal responsibility and a personal scrutiny: somebody must sweat blood with gift money if its effect is not to do more harm than good."

Societies and Academies.

PARIS.

Academy of Sciences, July 16.—M. Albin Haller in the chair.—L. C. **Jackson** and H. **Kamerlingh Onnes**: The magnetic properties of gadolinum ethylsulphate at low temperatures. The determination of the magnetic susceptibility of the powdered salt at temperatures ranging between 14°·56 K. (the lowest temperature obtainable with liquid hydrogen) and 291°·5 K., showed that gadolinum ethylsulphate obeys Curie's law, the product of the molecular susceptibility and the absolute temperature was constant. A single large crystal, the salt, although crystallising in the hexagonal system, was found to be magnetically isotropic.—J. B. **Senderens** and J. **Aboulenc**: The catalytic preparation of the aminocyclohexanols. Para- and ortho-nitrophenol are reduced by hydrogen under pressure (50 atmospheres) in the presence of nickel as catalyst. The reduction takes places in stages; at 90° C. aminophenol is produced, but if the temperature is raised to 180° C., additional hydrogen absorption occurs and aminocyclohexanol is obtained.—Charles **Nicolle** and E. **Conseil**: New facts concerning measles. Preventive vaccination. Conditions of contagion. The serum of convalescents confers a temporary immunity from infection: serovaccination, an injection of serum from a convalescent, followed 24 hours later by injection of blood from a patient with measles, confers a longer immunity. Contrary to the accepted view, the author maintains that one attack of measles does not confer permanent immunity, but a recurrence of the disease may be so mild (a rise of temperature only without eruption) that the nature of the disease on the second attack may escape recognition.—Philip **Fox**: Measurements of stellar parallax at the Dearborn Observatory. Data for 31 stars are given; each figure is derived from measurements of from 11 to 21 photographs.—M. **Holweck**: A high-power lamp for wireless telegraphy with removable parts. Diagram and description of a triode lamp of 10 kilowatt type now in use for postal service at the Eiffel Tower station. The lamp can be taken to pieces, the joints being either rubber or ground glass. For maintaining the vacuum, the lamp is permanently connected with the helicoidal molecular pump, described in an earlier communication (*Comptes rendus*, 177, p. 43).—A. **Dauvillier**: An experimental verification of the theory of Röntgen ray spectra due to a multiple atomic ionisation.—Pierre **Auger**: The secondary β-rays produced in a gas by the X-rays. By a modification of C. T. R. Wilson's method, taking simultaneous photographs in two perpendicular directions, information has been obtained about the trajectories of the electrons torn from the atoms of a gas by a bundle of X-rays.—M. **Escher**: The polonium carried down with bismuth hydrate in soda solution. When an acid solution containing bismuth and polonium is precipitated with soda, the polonium is distributed between the precipitate and the solution. The distribution of the polonium between the two phases is a function of the number of molecules of bismuth and of soda present in a given volume of the mixture. Two sets of experimental results are given in graphical form.—N. **Yannakis**: The vapour pressures of mixtures of hydrochloric acid and water.—P. Mondain **Monval**: The allotropic transformation of ammonium nitrate at 32° C. From the law of solubility given by Le Chatelier, it follows that two varieties of the same salt having different latent heats of solution should have different solubility curves, and at their point of

intersection, the two curves having different directions, should show an angular point. Determinations of the solubility of ammonium nitrate at eleven temperatures between 26·7° and 39·2° C. and calorimetric experiments on the same salt at 28° C. and 36° C. give results confirming the views of Le Chatelier.—P. **Laffitte**: The propagation of the explosive wave. A study by the photographic method of the explosion of mixtures of carbon bisulphide and oxygen in spherical glass vessels.—Mlle. **Chamié**: The ionisation produced by the hydration of quinine sulphate.—Albert **Colson**: The range of the displacement of equilibrium.—E. **Decarrière**: The catalytic oxidation of ammonia by air in contact with pure palladium. The yield of oxidised nitrogen is a function of the temperature of the catalyst, the percentage of ammonia in the gas entering, and also of the physical state of the metal. The results of experiments on the effects of the last factor are given.—André **Job** and André **Samuel**: Oxidation phenomena in the complex nickel cyanides: valence, co-ordination, coloration.—M. **Marange**: The identification of cocoa butter by miscibility curves.—M. **Haehl**: *p*-Chlorodiphenylsulphone. The chlorodiphenylsulphone prepared by Beckurts and Otto has been prepared by another method and is shown to be the para compound.—L. **Bert**: The chloride of cumylmagnesium.—Mlle. N. **Wolff**: The furfural- and difurfural-γ-methylcyclohexanones.—R. **Fosse** and A. **Hieulle**: Xanthyl-allantoin. The precipitation of this compound from an acetic acid solution serves to identify allantoin, and to precipitate it from solution containing very small proportions.—A. **Mailhe**: The preparation of petroleum starting from vegetable oils. Dry distillation of rape oil with zinc chloride gave more than 50 per cent. of hydrocarbons consisting of paraffins and unsaturated ethylene derivatives.—André **Helbronner** and Gustave **Bernstein**: The action of the antioxygens on rubber. Crude depolymerised rubber is preserved from oxidation by the presence of small proportions of antioxygens, such as tannin or hydroquinone. Vulcanised rubber thus treated does not show the usual effects of ageing.—Paul **Woog**: Direct observation of the hydration of hydrocarbons.—A. **Loubière**: A new genus of Pyrenomycetes.—Emile F. **Terroine**, R. **Bonnet**, and P. H. **Joessel**: The influence of temperature on the energy yield in germination.—A. **Polack**: The correct form of the experiment on the chromatism of the eye by the partial closing of the pupil.—R. **Faillie** and J. P. **Langlois**: The vertical oscillation of the centre of gravity of the body while walking down an inclined plane.—Mme. Anna **Drzewina** and Georges **Bohn**: The influence of light on the activating power of the sperm of the sea urchin.—Ch. **Dejean**: Rôle of the middle layer in the assemblage of the first beginnings of the eye.—P. **Lecène** and H. **Bierry**: The demonstration of the presence of sucrase in the wall of the mucoid cysts of the ovary.

CALCUTTA.

Asiatic Society of Bengal, July 4.—J. Coggin **Brown**: On the occurrence of *Ostrea gryphoides* Schlotheim in Calcutta. Specimens were found near the surface in excavations for a new building in Calcutta. They provide no new evidence on the question of a former extension of the sea over the present site of Calcutta.—H. C. **Das-Gupta**: On the fossil Pectinidæ from Hathab, Bhavanagar State (Kathiawar).—P. N. **Missra**: Lakshman Samvat. Calculation of European equivalent dates for 16 Lakhsman Samvat dates on various assumptions as to the beginning of the era.—H. C. **Ray**: Allusions to Vāsudeva Kṛishṇa Devakīputra in Vedic literature. Vāsudeva Kṛishṇa is mentioned not only in the Epic and the Purānas but also in at least two works of the Vedic literature.

CAPE TOWN.

Royal Society of South Africa, May 16.—Dr. A. Ogg, president, in the chair.—P. A. **van der Bijl**: Notes on some South African Xylarias.—A. **Ogg**: The crystalline structure of the alkaline sulphates. In conjunction with Mr. Lloyd Hopwood it was shown that the *crystal unit* of alkaline sulphates contains four molecules. With sulphur atoms at the corners and the face centres, and with the nitrogen atoms at the centres of each of the eight rhombs into which the unit can be divided by planes through the centre of the unit at right angles to one another and parallel to the faces, we can build up a structure which explains the structure of the ammonium sulphate crystal. The nitrogen atoms lie at the centre of a tetrahedron of hydrogen atoms, each hydrogen connecting up to an oxygen atom, which in turn connects up to a sulphur atom. In the structure for potassium, rubidium, and cæsium sulphates, if the metals with sulphur lie along the diagonal of the 100 face of the unit, the length of the diagonal, assuming Bragg's values for the atomic diameters, agrees with those found from X-ray measurements.

WASHINGTON, D.C.

National Academy of Sciences (Proc. Vol. 9, No. 6, June).—L. P. **Eisenhart**: Another interpretation of the fundamental gauge-vector of Weyl's theory of relativity.—G. Y. **Rainich**: Tensor analysis without co-ordinates. A method of deriving the theory of surfaces without introducing notions having no intrinsic significance such as transformations, covariants, and contravariant quantities, the fundamental tensor g_{ij} etc.—A. B. **Coble**: Geometric aspects of the Abelian modular functions of genus four (III.).—H. D. **Curtis**: On irregularities in the velocity curves of spectroscopic binaries. The spectrographic velocity curves of some of the Cepheid variable stars seem to fit elliptical velocity curves, each with a single oscillation or hump which occurs near the time of maximum velocity of approach. This is in agreement with Duncan's theory of a large and tenuous star rotating about a darker companion in a slightly resisting medium.—W. J. **Luyten**: On the form of the distribution law of stellar velocities. The distribution and space velocities of the stars which have been observed within a sphere with the sun as centre and of radius 10 parsecs seem to fall on a simple logarithic error curve.—C. G. **Abbot** and colleagues: The solar prelude of an unusual winter. The mean monthly values of the solar constant determined at Mount Harqua Hala, Arizona, and Mount Montezuma, Chile, decreased throughout 1922 and the early part of 1923. This seems to have been related to unusual weather conditions in the United States.—C. E. **Mendenhall** and M. **Mason**: The stratified subsidence of fine particles. Suspensions of rock particles were allowed to settle in rectangular tubes across which a temperature gradient was maintained. Stratification occurred in the tubes where the amount of suspended material increases appreciably with depth, but too great a temperature gradient destroys any strata. The effect seems to be due to convection currents which circulate in definite layers.—M. **Mason** and C. E. **Mendenhall**: Theory of the settling of fine particles. An expression giving the position of layer boundaries is derived.

Experiments on two groups of tubes of suspensions show that the rate of fall of the layer boundaries is independent of the temperature gradient within wide limits, and the position of the layers is a function of concentration, time of settling, and thermal gradient.—E. H. **Hall**: The quasi-equation $P = TdV/dT$. If two plates of dissimilar metals are connected through wires made of the same metals, the plates show opposite charges. If unit charge is made to pass from the positive to the negative plate, heat is absorbed; this includes the Peltier effect at the junction. Assuming a mass-law of equilibrium between the ions and electrons of the metals, heat-energy is absorbed at the free surface of the metals in addition. This added to the Peltier effect gives nearer accordance with experimental results.—E. F. **Nichols** and J. D. **Tear**: Joining the infra-red and electric wave spectra. A Hertzian doublet with minute platinum cylinders acted as the source of the waves. The receiver consisted of a Nichols radiometer in which the vanes were mica strips carrying thin deposits of bright platinum. A new form of reflecting echelon analyser was used for the wave-length measurements. By these means electric waves of lengths varying from 7 mm. to 0·220 mm. were produced and detected, thus overlapping previous measurements for infra-red radiation (*e.g.* Rubens and Von Baeyer, 0·320 mm.).

(Proc. Vol. 9, No. 7, July).—A. E. **Kennelly**: On the constant ratio of mean-to-mid potential or current at successive equidistant points along a uniform electric conducting line, real or artificial, in the steady state. The theorem also applies to tables of hyperbolic sine or cosine functions where the angle increases in uniform arithmetical progression, and to tables of $\epsilon^{\pm\theta}$ where θ increases in uniform arithmetical progression.—R. **Brown**: Some recent measurements of transatlantic radio transmission. A high-power vacuum tube transmitter with an output of 200–300 amperes of 57,000 cycle alternating current is used at Rocky Point, Long Island, producing continuous radiation of about 5250 metres wave-length. A receiver in London evaluates the absolute root mean square of the electric field produced. The field rises sharply to a maximum during the period when the route is in darkness, but does not exceed the value calculated from the Austin-Cohen radio-transmission formula. Good night transmission seems to be due to a diminution of losses by absorption rather than to focussing effects.—C. B. **Davenport**: Body build and its inheritance. The ratio, chest girth to stature, or alternatively weight to stature, was used as an index of build in man. A solid figure generated by combining the variability curves with developmental curves shows two main ridges, indicating two main types, medium build and fleshy; the latter seems to refer to the progeny of fleshy and slender strains, showing dominance of fleshiness.—G. C. **Evans**: A Bohr-Langmuir transformation. Mathematically, Langmuir's completely static atom can apparently be shown to be equivalent to the Bohr atom with a circular orbit.—G. A. **Miller**: Form of the number of the subgroups of a prime power number.—G. **Breit**: (1) The interference of light and the quantum theory. Assuming that radiation momenta are transferred in quanta, expressions are derived which represent the effect of (*a*) a diffraction grating of infinite width, (*b*) a finite number of narrow, parallel, co-planar and equal slits, and (*c*) a slit of finite width. (2) Note on the width of spectral lines due to collision and quantum theory. The amounts of the broadening appear to be nearly equal to those given on the wave theory of light and can be accounted for similarly.—P. A. **Ross**: Change in wave-length by scattering. Experiments were made to detect the change in frequency of X-rays and γ-rays on scattering by paraffin, aluminium, and graphite suspected by Compton. Relevant equations indicate that the change of wave-length is independent of the primary wave-length. No such shift was observed by scattering the green mercury line at 180° from paraffin. Using photographic methods and X-rays, the required displacement (about 0·025 Å.) was observed by scattering the α_1 and α_2 lines from calcite at 90° from paraffin. Another unshifted line was recorded.—E. L. **Nichols**: Notes on germanium oxide. The powdered oxide was heated, side by side with a uranium oxide surface, in an oxyhydrogen flame. The radiation of uranium oxide being practically equivalent to black-body radiation, a comparison of the two gives approximately the radiation of germanium oxide in terms of black-body radiation. Preponderance of blue at lower temperatures and of red near fusing point are the characteristics. The reversal point is 1225° C. and melting point 1400° C.—C. **Wissler**: The correlation of respiratory and circulatory data for adult males. Pulse rates in men before and after exercise show a high correlation (+0·73); pulse rate correlates with respiration rate (+0·45) but not with blood pressure and chest mobility. Breathing rate and chest mobility appear to be complementary (correlation −0·46), *i.e.* a man with a mobile chest automatically breathes deeply.—T. W. **Vaughan**: Studies of the larger tertiary foraminifera from tropical and subtropical America. There appears to be no evidence of deposits of Lower Cretaceous age at relatively shallow depths in Florida. Deposits of middle and upper Oligocene age occur in northern Colombia. An evolutionary sequence from ancient Eocene forms of Lepidocyclina with meridional chambers, pointed inner ends, and curved outer walls, to species with hexagonal and rhomboid chambers, is suggested.—S. O. **Mast**: Mechanics of locomotion in Amœba. Three regions are differentiated in *Amœba proteus*: (*a*) a central elongated fluid portion (plasmasol); (*b*) a granular layer surrounding the fluid (plasmagel), and (*c*) a thin elastic surface membrane (plasmalemma); (*b*) and (*c*) are semipermeable and (*a*) is hypertonic. Local swelling of the plasmagel occurs at the tip of pseudopodia with liquefaction on the inner surface at the posterior end. Gelation of plasmasol occurs at the outer posterior border of the swelling. Thus a forward flow is produced which is translated into motion by the adhesion of the plasmalemma to the substratum.

The Helicopter: is it worth a Prize?

JULES VERNE is responsible for the idea of the helicopter, and as a writer of works of imagination he invented devices with ease. The aeronautical engineer asked to produce a helicopter must recognise some limitations of his powers, and one is led to wonder whether the author of "The Clipper of the Clouds" could have solved the problems associated with the materialisation of his ideas. Press comments on the official conditions for the test of a helicopter, and the wording of the rules by the Air Ministry, raise the principle involved in this idea in a form of considerable interest to men of science. In the *Times* of May 11 appeared the following paragraph:

"Still, the Air Ministry cannot afford to neglect the possibility that some practical helicopter may suddenly be evolved, and by their action they have made reasonably sure that any such development will come before their notice."

To guard against the possibility of ignorance in this particular direction, prizes to the total value of 50,000*l.* have been offered; the cost of the aeronautical research at the National Physical Laboratory is about 23,000*l.* per annum. The construction of the Brennan helicopter by the Air Ministry at Farnborough is variously estimated to have cost from 60,000*l.* to 100,000*l.*; lack of separate accounts for research and *ad hoc* experiments make it difficult to estimate the cost of scientific research at Farnborough, but it is probably of the same order as that at the National Physical Laboratory. It is believed to be inadequate for systematic progress on the full scale, with the result that Britain is far less active than America.[1]

Is the Air Ministry in danger of losing the substance for the shadow in giving prominence to a policy based on accidental strokes of genius rather than on patient and certain inquiry? Scientific workers at least will realise how foreign such a policy is to their own work.

Leaving this issue, which needs no elaboration in the columns of NATURE, it is interesting to examine the prize scheme on technical grounds. A passage which crystallises the underlying idea says: ". . . . a successful helicopter—that is, a machine capable of rising vertically from the ground under its own power, . . ." thereby indicating the property to which chief importance is attached as that which allows an aircraft to leave the ground and return to it without the high forward velocities of 50-60 miles per hour normal to the aeroplane. Such a property added to an aeroplane would be welcomed by all

[1] See the Wilbur Wright memorial lecture before the Royal Aeronautical Society by Dr. Ames, Chairman of the Executive Committee of the American National Advisory Committee for Aeronautics (1923).

interested in flying, but technical opinion, as voiced in public discussions, considers that in attaining this feature by the helicopter almost every other desirable quality of a flying machine is sacrificed.

Criticism has turned largely on the lack of efficiency and safety in the helicopter. The airscrew is not a new device and the principles of its operation are well established; efficiencies of 75 per cent. can be reached and utilised in the aeroplane *because it is an aeroplane*. This point is of some interest and merits further study; all heavier-than-aircraft are supported during flight on the sacrificial principle, that is, something else is driven down to keep the aeroplane from falling under the influence of gravity. In the aeroplane the utilisation of power in producing lift is indirect, for the airscrew is made to overcome the resistance of the aeroplane, whilst the wings produce the down current, and by reaction, the lift. This lift may be nine times as great as the thrust of the screw, and is rarely less than three times its amount.

The arrangement is efficient because the wings are large organs; it is the momentum generated per second which produces lift, whilst the power required is roughly measured by the energy thrown away in the downwardly moving air. The loss of energy for a given lift decreases progressively as the area of the downward stream is increased, and hence the efficiency of the aeroplane follows, in part, from the use of large wings. If the helicopter is to compete with the aeroplane on the score of efficiency its lifting screws must be large.

As the extreme case of large size, consider two aeroplanes flying in a circle and connected by some framework at present undefined, except that it supports a car at its centre. A first problem is immediately indicated—means must be provided for keeping the car free from rotation. If the aeroplanes are far enough apart their efficiency will remain as before, and as supporters of weight are fully effective. As a means of getting from place to place the combination is, of course, useless; modification of the problem still leaves us with the obvious conclusion that, whereas the wings of an aeroplane travel directly from point to point, those of the helicopter follow sinuous and longer paths. The argument seems to be fundamental and to exclude the helicopter from the degree of efficiency as a means of transport which can be reached with a good aeroplane.

Returning to our example, it will be found that a new factor enters into the problem as the two aeroplanes fly in smaller and smaller circles; each passes through the downwash produced by the other and by itself on previous passages. If near enough, this interference becomes very important, and it constitutes the only real difference between the helicopter as hitherto projected and the airscrew as commonly used. In looping, pilots frequently feel a bump on closing the loop, although some fifteen seconds has elapsed since the first passage and the distance travelled has been about 1000 ft. A further illustration explained on this principle arises from the observation that an increase of thrust arises from the sideways moving of a stationary airscrew, and therefore may be expected in a helicopter when used for transport.

All this is known, and the principles were laid down many years ago by the late Lord Rayleigh and others. Combined with modern data, it is possible to use existing knowledge to predict the limits of efficiency of a helicopter and to rely on the results. The design of the structure which holds the wings together presents greater difficulties, and attempts to build helicopters now may react favourably on structural design, but probably at a cost far in excess of that required to produce the same results by research.

Most of the attempts at helicopter design have led to screws some 40 to 60 ft. in diameter moving on the periphery at speeds of 70 to 100 m.p.h. Devices produced in more than one country have lifted themselves into the air, but little has been attempted in free flight. The Air Ministry has announced the development of the Brennan helicopter to the stage of lifting itself, and only ten per cent. of the prize money is allocated to the extension of this performance from a few feet to vertical flight up to 2000 ft. in a light breeze.

The rest of the competition relates to transport and control. One particularly hazardous requirement is that the helicopter ". . . must descend vertically from a height of not less than 500 ft. without engine. . . ." It is a crucial test which, I believe, would involve certain death to the pilot who attempted it in the helicopters so far devised. In the case of engine failure, the helicopter at best is less effective than a parachute having an area equal to its blade surface, and is quite unable to provide an adequately small rate of descent. At its worst it is far inferior to this. In all circumstances the aircraft will require control, and the solutions hitherto proposed do not inspire confidence. It is evident that even the essential principles of a happy solution depend on that stroke of genius for which the Air Ministry is appealing and which it appears to think only needs a monetary stimulus to become operative.

Unlike the helicopter, the aeroplane does not lose its lift when the engine fails. It must perforce descend, but all its controls remain intact and danger comes only if the available alighting ground is unsuitable. Safety in aeroplanes is a subject for insistent inquiry,

but marked improvement appears to be near realisation. Safety in a helicopter presents unsolved difficulties.

What, then, is the purpose of the helicopter? Presumably the use is to be military and secret. Outside opinion has not made any satisfying guess, and in these circumstances men of science, as well as aeronautical engineers, are disturbed by the evidence which this prize scheme gives as to the direction of Air Ministry policy. It is not expected that any appreciable part of the fund will be called on, and the whole sum would not be grudged to the producers of a new and useful type of aircraft. The fear is that, in following a "will of the wisp," insufficient attention will be given to systematic research on which, in the past, British constructors have been able to maintain a high quality for their productions. L. Bairstow.

Life of a Naturalist and Teacher.

The Days of a Man: being Memories of a Naturalist, Teacher, and Minor Prophet of Democracy. By David Starr Jordan. Vol. 1: 1851–1899. Pp. xxix + 710 + 56 plates. Vol. 2: 1900–1921. Pp. xxi + 906 + 56 plates. (Yonkers-on-Hudson, N.Y.: World Book Co.; London: G. G. Harrap and Co., Ltd., 1922.) 15 dollars.

"THE Days of a Man" is the title chosen by Dr. David Starr Jordan for his autobiography. Dr. Jordan, who was born in 1851, has been for many years the leading ichthyologist in America, and is the author of a large number of memoirs on fishes, generally written in collaboration with his pupils. Of these the best known is the monumental "Fishes of North America" (1896–1900) by Jordan and Evermann, but perhaps his work on the Fishes of Japan marks the greatest advance, for these had been comparatively little studied until his collecting expedition in 1900.

Dr. Jordan's early tastes were for botany, in which he was so well-versed that even as a student at Cornell he was teaching this subject. He was first led to study fishes by attending a vacation course for science teachers organised by Louis Agassiz, and for many years afterwards he generally spent his vacations in collecting and reporting on the fishes of some region, at first on his own account and afterwards for the American Government, which ultimately sent him so far afield as the Sandwich Islands. It is perhaps worth mention that he invented the name "Rainbow Trout" in 1878.

Notwithstanding his distinction as an ichthyologist, we are inclined to think that Dr. Jordan's best work has been educational; and this applies even to ichthyology, since nearly all American ichthyologists were taught by him. In 1879, at the early age of 28, he became professor of natural history in the University of Indiana, and did so well that in 1885 he was elected president. He had now an opportunity to show his genius for organisation and to put his educational ideas into practice. There were many difficulties, but he overcame them. In his own words:

"In 1886 I made some sweeping changes, doing away with the fixed curriculum and adjusting the work so that practically all the subjects hitherto taught in the University, being elementary in their nature, were relegated to the first two years. Further than this, we instituted a 'major subject' system, by which each junior or third-year student was required to choose a speciality or 'major,' and to work under the immediate advice of his 'major professor,' whose counsel in details he was obliged to secure. An individual course of study was thus framed for each one. This system, which has now stood the test of more than thirty years in Indiana, Stanford, and elsewhere, was originally developed by a committee consisting of Dr. Hans C. G. von Jagemann, Dr. William Lowe Bryan, and myself. Its purpose was to enable every one to make the most of his four college years, by seeking the best teachers and the subjects best suited to his tastes and capacity."

Whilst carrying out these and other reforms Dr. Jordan undertook propaganda work, giving lectures that made the aims and purposes of the university understood in the State of Indiana. At the same time he showed wise judgment in making new appointments, Campbell, the botanist, and Branner, the geologist, being two of his early choices.

Jordan's success at Indiana was so great that in 1891 he was the obvious man to select as president of the newly established Stanford University. Here he had a congenial task, to plan out from the beginning the lines on which a university should be run and to select what men he liked to help him in the work. At first all went well, but in 1893 Stanford's death led to unexpected legal difficulties with regard to his estate, which seriously hampered the university, and after this matter had been satisfactorily disposed of came the earthquake of 1906, which wrecked a great part of the university buildings. On the morning of the earthquake Dr. Jordan received an invitation to become secretary of the Smithsonian Institution; in other circumstances he would probably have accepted, but he felt that it was his duty to stay at Stanford, and he did so, becoming Chancellor of the University in 1913, and finally retiring in 1916, at the age of sixty-five. He has good reason to be proud of the flourishing condition and the high reputation of Stanford, and of the success of its graduates.

Dr. Jordan is a man with high ideals and strong convictions, and he is a keen observer who has travelled in many lands. His views on men and matters are

full of interest and demand attention. He is strongly opposed to the use of alcohol and tobacco, and he regards war as an out-of-date and anti-democratic method of settling disputes. At one period he gave much attention to the reform of the American civil service, and in recent years he has devoted a great deal of his time to lectures in America, Europe, and Japan in the cause of international peace, a subject on which he has written several books. When a man's life has been so strenuous and so varied the writing of an autobiography is a task of some magnitude. But it was well worth doing, and it has been well done. We congratulate Dr. Jordan and we thank him.

C. T. R.

The Structure of the Atom.

(1) *The Structure of Atoms.* By Prof. Dr. Alfred Stock. Translated from the Second German edition by S. Sugden. Revised and enlarged. Pp. viii + 88. (London: Methuen and Co., Ltd., 1923.) 6*s*. net.

(2) *La Théorie des quanta et l'atome de Bohr.* Par Léon Brillouin. (Recueil des Conférences-Rapports de Documentation sur la Physique. Vol. 2, 1re Série, Conférences 4, 5, 6. Édité par la Société *Journal de Physique.*) Pp. 181. (Paris: Les Presses universitaires de France, 1922.) 15 francs.

(3) *Institut International de Physique Solvay.* Atomes et électrons. Rapports et discussions du Conseil de Physique tenu à Bruxelles du 1er au 6 avril 1921 sous les auspices de l'Institut International de Physique Solvay. Pp. vii + 272. (Paris: Gauthier-Villars et Cie, 1923.) 20 francs.

THE problem of the structure of the atom is one which for many years has exercised a fascination for the scientific mind. Its solution demands the correlation of phenomena from many branches of physics and chemistry, and the repercussion of the current ideas on the subject makes itself felt over a correspondingly wide field. It is a subject on which no worker in physics or chemistry dare allow his knowledge to become out-of-date, and in which other scientific workers take an interest which is by no means entirely extraneous. Owing partly perhaps to the distinction and lucidity of some of its famous exponents, it has also aroused the interest of a wider non-scientific circle and has won for itself a distinctly "good press." In the circumstances it is not surprising that books on the subject, addressed to one or other of these numerous classes of potential readers, should appear at frequent intervals.

(1) Prof. Stock's little volume is addressed to the chemist, and contains a resumé of a series of lectures delivered by him to the works chemists of a well-known German manufactory. He attempts to remove what he describes as the "thorns of theoretical physics and mathematics" which beset the tender feet of the chemist who would wander in the "Wonder-garden" of atomic structure. He has, in fact, pruned so remorselessly that the book resembles rather a sketch plan than a garden, showing little more than the direction of the main paths and the openings into some of the principal alleys. To abandon the metaphor which Prof. Stock himself suggests in his preface, the book contains a fairly complete, but very brief, summary of the various phenomena which have a bearing on the problems of atomic structure; and a still briefer exposition of some of the current theories. A very interesting volume could be written around the synopsis thus provided. The fact that positive rays and the quantum theory occupy little more than half a page each, while the theory of relativity is consigned to a footnote, indicates the extreme condensation which has necessarily been employed to compress so vast a subject into so narrow a space. The reader will, however, learn from its pages how much there is to be learnt, and a brief bibliography points out the principal sources from which the English reader can obtain further information.

(2) M. Léon Brillouin's book "La Théorie des quanta et l'atome de Bohr" is addressed to the serious student of the subject. It forms the second volume of the series of reports which the Society *Journal de Physique* is publishing on various aspects of modern physics, and maintains the high standard which was set by M. de Broglie in his initial volume, "Les Rayons X." Probably no student of physics is entirely ignorant of Planck's quantum theory, and its application to thermal radiations, or of Bohr's daring and brilliant extension of the quantum principle to the nuclear atom of Sir Ernest Rutherford which resulted in the calculation of the hydrogen spectrum, and the evaluation of Rydberg's constant; certainly one of the greatest achievements of theoretical physics in modern times.

The later developments of the theory are far less known, nor has it been, up to the present, at all an easy matter to become acquainted with them. The original memoirs of Bohr and other distinguished workers on the same problem are scattered through the pages of many periodicals in many languages. Moreover, as was inevitable in a problem so complex as that of the motion not of three only but of many attracting and repelling particles, there have been numerous false starts and incorrect conclusions, and it has not infrequently happened that, after mastering with some difficulty one of these essays, the student has found to his chagrin that it has been superseded by later work. It must be confessed, too, that the pioneers

of the theory, in their preoccupation with the extension of the subject, have not had too much pity on their weaker brethren, and it has not always been easy to discover either the exact nature or the physical basis of some of the principles to which they appeal. M. Brillouin's lucid and authoritative survey of the whole subject is, therefore, particularly welcome and valuable.

It was a happy inspiration on the part of M. Brillouin to preface his main thesis with two preliminary chapters on the quantum theory of radiation. It is a subject on which the author has himself done much valuable work, and his excellent, though brief, account provides a firm basis for the developments which follow. The succeeding chapters on the theory of Bohr, on its applications to atomic structure, and in particular the account of the principles of selection and correspondence, are equally illuminating.

It is not to be expected, from the very nature of the subject, that the volume should be easy reading. The author has not shirked the very considerable mathematical difficulties which are involved in the theory. He has, however, minimised them as far as is consistent with a proper understanding of the argument. Though it cannot be promised that the average student of physics will find his progress through the volume an easy one, he may be assured that his labours will be rewarded by a completer knowledge and a deeper appreciation of this important subject.

(3) It is in no way derogatory to M. Brillouin's excellent treatise to say that it is surpassed in interest by the report of the proceedings of the council of distinguished physicists who assembled in Brussels in 1921 under the presidency of Prof. Lorentz and under the auspices of the Solvay Institute. The number and distinction of the participants, each a master in his own particular branch, and the variety and importance of the subjects considered would in themselves suffice to raise high expectations. It may be said at once that, in the main, these expectations are fully realised by the volume which is now to hand.

Each of the twelve closely related subjects chosen for discussion was introduced at the Conference by a report on the actual position of the subject, and these reports make up the main part of the text. Thus Sir Ernest Rutherford reports on the structure of the atom, M. de Broglie on the quantum relation in the photoelectric effect, Prof. Kamerlingh Onnes contributes an account of his work on paramagnetism at low temperatures and on the super-conductivity of certain metals at low temperatures. Prof. Bohr gives an account of the application of the theory of quanta to atomic problems, which is supplemented by a report from Prof. Ehrenfest on the principle of correspondence.

It is natural that the different authors should develop their subjects in slightly different ways, and should assume slightly different degrees of previous knowledge amongst their distinguished colleagues, or perhaps we should rather say among the wider circle of readers for whom the reports were ultimately destined. In most cases, however, the reports are so well conceived and so lucidly expressed that the reader with only an elementary knowledge of the subject will have little difficulty in following a very considerable part of them. It is, in fact, an open question whether such a reader, at the expense of a little judicious "skipping" of the more recondite portions, would not attain a better appreciation of the present position of atomic physics from this volume than from many of the works ostensibly written for his special benefit. This, of course, does not apply to the one or two reports of a mathematical character, such as the profound suggestions of the president, Prof. Lorentz, in his notes on the theory of electrons which opens the volume.

In addition to their expository value, these reports have the great merit of opening up new avenues for discussion and experiment. In dwelling on the very considerable achievements which have been brought about, partly by the application of quantum theories to atomic problems, it is apt to be overlooked that these theories present formidable difficulties in addition to the fundamental one of explaining themselves. These difficulties are clearly raised in the discussions which follow the reports, and perhaps in none of them more clearly than in Prof. Barkla's discussion of M. de Broglie's report on the photoelectric effect. The discussions, which are excellently reported, are full not only of scientific but also of human interest. To the physicist, whether mathematical or experimental, in need of a subject for research they offer an ample choice of problems of fundamental importance.

It is to be regretted that so long an interval has been allowed to elapse between the meetings of the council and the publication of its report. It was not to be expected that the members of the council would allow two years to elapse before attempting the solution of some of the problems raised, and still less to be expected that their attempts should be entirely without success. In some particulars, therefore, the subject has advanced beyond the stage indicated in the reports. In the main, however, this applies only to minor problems. If it is true that intellectual satisfaction results from the discovery rather than from the knowledge of truth, a perusal of this volume will convince the reader that in this portion of physics he may confidently expect to find intellectual satisfaction for many years to come.

J. A. C.

The Ascent of Sap.

The Physiology of the Ascent of Sap. By Sir Jagadis Chunder Bose. (Cossimbazar Endowment Publication.) Pp. xv+277. (London: Longmans, Green and Co., 1923.) 16*s*. net.

THE author supplies in this book further ingenious experimental devices in which use is made of automatic recording methods and of various methods of magnifying small movements. The rate of ascent of sap is measured by a mechanical method recording the re-erection of a drooping tissue as sap enters it, and by an electrical method in which a quadrant electrometer is used to determine change of electromotive force between two points, one of which changes in turgor. By placing one electrode, carefully insulated save at the point, upon a graduated micrometer screw movement, the instrument becomes an electric probe by which the most vigorous changes in turgor are traced in the Dicotyledon stem to the living tissues in the region between inner cortex and vascular tissue.

The usual simple potometer experiment is modified into a recording potograph, whilst an ingenious bubbling method is introduced to measure the absorption of water by a cut shoot, and thus indirectly its transpiration, under varying conditions.

Many interesting observations are recorded in this account of work in the Indian climate, notably the report upon the exudation of sugar solution from cut surfaces in the stem apex or the inflorescence of the palm. This exudation is shown to be quite independent of any direct supply of sap from the absorbing system of the root.

The author's attempt to reinterpret the phenomena of the ascent of sap in the light of his new experiments is not convincing. As the result of a discussion of earlier work, mainly based apparently upon the English translations of the text-books of Haberlandt, Jost and Pfeffer, it is concluded that transpiration from the leaf and exudation from the root do not provide an adequate mechanism for the ascent of sap, whilst the rôle of osmosis is dismissed in two paragraphs. As opposed to this inadequate mechanism is advanced "a theory of cellular pulsation according to which the liquid is injected by the living cells into the wood-vascular tissue."

Later, the role of the xylem vessel seems practically to disappear—"The uni-directional propulsion of sap depends upon a sequence of pulsation from cell to cell. The sap expelled during the contraction of any one cell is absorbed by a cell higher up during its phase of expansion. There is then a propagation of a wave of contraction, preceded by one of expansion, in consequence of which the sap is, as it were, squeezed forward. A succession of such waves maintain the continuous ascent of sap." Though this may be clear to the author, the reviewer feels himself no nearer an understanding of the actual movement of sap in the plant. The demonstration of this mechanism rests upon experimental evidence that temperature, poisons, and various other external factors affect similarly sap movement and the pulsating mechanism, and upon a demonstration of electro-motive forces in tissues which are assumed to be manifestations of changes in cell turgor.

The experimental evidence is, however, not employed critically; thus it is argued that transpiration is not essential to the ascent of sap because the author's mechanical method shows a rapid rise of sap in a partially wilted chrysanthemum shoot when the cut end is placed in water, although the surface, both stem and leaf, had previously been coated with vaseline.

A Metric Campaign.

World Metric Standardisation: An Urgent Issue. A Volume of Testimony urging World-wide Adoption of the Metric Units of Weights and Measures—Meter-Liter-Gram. Compiled by Aubrey Drury. Pp. 524. (San Francisco: World Metric Standardisation Council, 1922.) 5 dollars.

FOR several years an intensive propaganda has been carried on by the "World Metric Standardisation Council" on both sides of the Atlantic in furtherance of the objects indicated in the title of this book. Apparently self-appointed, its executive includes a number of men prominent in politics, commerce, and engineering, mainly resident in the United States, but representing also Canada and Great Britain, and the council has members and correspondents in almost all countries. It is under the direction of this body that the volume before us has been compiled, bringing together a vast amount of information and data regarding the "master standards" of the world, and aiming, of course, to promote their adoption in the United States and the British Empire for all commercial transactions. It is pointed out in the introduction that far less opposition has been raised to the adoption of the litre and gram than to the metre, which is very much more closely related to industrial processes than the units of mass and volume; but on the other hand, it is not proposed to impose the use of metric measures upon production—only upon distribution.

A large proportion of the work consists of quotations from the reports of committees which have investigated the subject at various times, the writings and speeches of individuals, and Bills which have been introduced into Congress and Parliament, as well as resolutions

recorded by public bodies in favour of the metric movement; there are also lengthy lists of municipal authorities, commercial associations, and manufacturing companies which have definitely adhered to the proposed reform. The rest of the work is devoted mainly to the history of metric legislation in the United States and the British Empire, selected articles on the metric system, and a comprehensive bibliography.

From what has been said, it will be seen that the contents of the book are somewhat heterogeneous, and in parts reminiscent of a collection of press cuttings; it necessarily presents only one aspect of the question, being propagandist in the extreme. We cannot conceive of any reader faithfully perusing its pages from cover to cover, any more than he would an encyclopædia, but as a storehouse of opinion, anecdote, and similar material for the apostle of metric weights and measures to draw upon it will exercise considerable influence upon the rate of progress towards "world metric standardisation." A good index facilitates reference to the principal topics and authorities dealt with in the book, which is dedicated to James Watt as the originator of the decimal method of measurement, and contains many portraits of its advocates.

In Great Britain there is at present little evidence of a popular demand for the compulsory adoption of the metric system, though Chambers of Commerce and the Trade Union Congress annually pass resolutions advocating the reform; the Decimal Association, whilst continuing its metric propaganda, is devoting attention mainly to the decimalisation of the coinage, with the adoption of the "high-value penny" (one-tenth of a shilling, the latter retaining its present value) as the principal item in its programme. In the United States, where the benefits of decimal coinage are already enjoyed, strong efforts are being put forth to add thereto the advantages of decimalised weights and measures, and a Bill is now before Congress for that purpose. The energy devoted to the campaign in that country, of which the volume under review affords striking evidence, commands our admiration; but it must be admitted that the opposition to the movement in certain quarters is both bitter and powerful.

A. H. A.

Our Bookshelf.

Catalogue of Scientific Papers. Compiled by the Royal Society of London. Fourth Series (1884-1900). Vol. 18: Q-S. Pp. iv+1067. (Cambridge: At the University Press, 1923.) 9*l.* net.

FROM the outset this monumental work has occupied a very high position as a trustworthy work of bibliographical reference—due to the judicious extension of its range, the faultless accuracy of its entries, and the critical examination to which its author headings have been subjected. It is international in scope and appeal, but of purely British manufacture, and is now nearing the completion of the first century of its labours, for the final volume of the present series is promised next year. At first sight it might appear a tolerably simple matter to assign to their proper author headings a collection of carefully prepared transcripts of the titles of papers; but this view would not be confirmed by any cataloguer or indexer of experience. Initials of the forenames of writers have to be expanded, entries under writers of the same name and forenames to be distinguished, pseudonyms to be unmasked, and changes of name accounted for. With the spread of Western science to the East, the difficulties of accurate editing have multiplied. Nevertheless the standard of sound workmanship set by the editors of the earlier volumes has been maintained.

No great loss, we think, has resulted from the partial elimination in the present series of references to serials containing reprints, abstracts or translations of original papers. The retention of these references in the case of papers written in the less familiar languages serves most practical purposes of research. We trust that in the concluding volume Dr. Forster Morley will furnish us with complete statistics of the number of papers and their authors for the period 1800-1900, together with a chronological table or graph showing the rate of growth of scientific periodical literature for the same period.

Handbook for Electrical Engineers: a Reference Book for Practising Engineers and Students of Engineering. Compiled by a Staff of Specialists. Edited by H. Pender and W. A. Del Mar. Pp. xxiii+2263. (New York: J. Wiley and Sons, Inc.; London: Chapman and Hall, Ltd., 1922.) 30*s.* net.

THE many engineering researches both theoretical and experimental which have been carried out in recent years have created a demand for handbooks which will give the practical results obtained in a way that can be readily understood. The principal articles in this work under notice are written by well-known engineers and professors. The arrangement is excellent and there is practically no overlapping. It contains more theory than is usually found in similar works. The mathematical symbols are very clearly printed, the diagrams are excellent, and the index is very complete and well arranged. Although there are many references to radio communication, "wireless" is not mentioned. We are pleased to see that both "ground" and "earth" are given. The word "hydrology" is used to denote the "science of water." In water power engineering, for example, hydrological data such as the rainfall, natural drainage, and the velocity of the stream are required.

The Evolution of the Conscious Faculties. By Dr. J. Varendonck. Pp. 259. (London: G. Allen and Unwin, Ltd.; New York: The Macmillan Co., 1923.) 12*s.* 6*d.* net.

THIS book contains much valuable matter in the shape of introspective analysis, experimental investigation, and critical examination of theories, of the mental faculties. Dr. Varendonck leaves the impression of an enthusiastic and competent student of

conscious processes. He takes Bergson and Freud as his directors. He follows Bergson in distinguishing two kinds of memory, but he names them reduplicative (Bergson's pure memory, the integral record of the past) and synthetic (Bergson's habit-memory). He also follows Bergson in the view that memory is an essential factor of perception. His method, on the other hand, closely follows the kind of analysis with which Freud has familiarised us in the "Traumdeutung," but unlike Freud he lays no emphasis on the sex motive, nor is he in any way obsessed with the idea of symbolism. It is a sane and useful discussion of the nature and origin of intelligence.

The Principles of Geography, Physical and Human. By Dr. E. G. Skeat (Mrs. Woods). Pp. 432. (Oxford: Clarendon Press; London: Oxford University Press, 1923.) 6*s*. 6*d*. net.

DR. SKEAT has produced an attractive book, fresh in outlook, inspiring and thoroughly readable. We miss with gratitude the wearisome reiterations of the ordinary run of text-books and find the author continually turning to original sources and taking new points of view. Both matter and style commend the book and give it a place by itself. The greater part treats of the physiographical side of geography, but the concluding section gives an excellent introduction to human geography. There are many well-selected diagrams, sketch-maps, and illustrations, and a copious bibliography. The book is too advanced for most school work, but should prove valuable to teachers of geography. Its careful use could not fail to improve the teaching of the subject.

The Contact between Minds: a Metaphysical Hypothesis. By C. Delisle Burns. Pp. x+138. (London: Macmillan and Co., Ltd., 1923.) 7*s*. 6*d*. net.

MR. BURNS has produced a very clear argument. It avoids the epistemological problem of intercourse, and the psychological problem of the genesis of knowledge, and narrows itself to the discussion of the nature of our knowledge of other minds. The traditional view that the existence of other minds is an inference is rejected, and it is held that the knowledge of them is "enjoyment" in the technical philosophical meaning of the term. Mr. Burns conceives knowledge realistically as the contemplation of objects compresent with the mind which knows itself in the contemplating. Other minds are known, he thinks, not as objects contemplated, but as our own mind contemplating. It is a thoughtful essay on a problem of deep interest.

Readable School Chemistry: a Book for Beginners. By J. A. Cochrane. (Bell's Natural Science Series.) Pp. x+84+8 plates. (London: G. Bell and Sons, Ltd., 1923.) 2*s*.

MR. COCHRANE'S book deals historically, and to a certain extent popularly, with the ground usually covered in a first year's course of chemistry. It contains interesting biographical details of the great founders of the science, and deals with their important researches. These are supplemented by brief notes on modern chemistry, and the book is well illustrated with portraits. Mr. Cochrane's book should be very useful and interesting to beginners in chemistry, and its very moderate price brings it within the reach of all students. On p. 30 the name should be "Brand," and on p. 64 "Warltire."

An Introduction to Theoretical and Applied Colloid Chemistry: "The World of Neglected Dimensions." By Prof. Wo. Ostwald. Authorised Translation from the Eighth German edition by Prof. M. H. Fischer. Second and enlarged American edition. Pp. xiii+266. (New York: J. Wiley and Sons, Inc.; London: Chapman and Hall, Ltd., 1922.) 12*s*. 6*d*. net.

THE new American edition of Wo. Ostwald's book on colloid chemistry is a translation from the eighth German edition. The author's lecturing tour in America appears to have taught him how to present the difficult subject of colloids in its simplest and most dramatic form. The great success of the book is a tribute to the completeness of the education thus received.

A Text-book of Inorganic Chemistry. By G. S. Newth. New and enlarged edition. Pp. xiii+772. (London: Longmans, Green and Co., 1923.) 8*s*.

NEWTH'S text-book has been found useful for so long that it needs no description. The new edition has been revised and brought up-to-date, and will be found as clear and accurate as former editions. The sections on modern advances are very readable, and this side of the subject has not been overdone. In one or two instances the revision has perhaps not been so complete as it might have been: the long descriptions of the Leblanc process and the chamber process seem out of proportion in comparison with the very short sections on the ammonia-soda and contact processes.

Electrical Horology. By H. R. Langmand and A. Ball. (Lockwood's Technical Manuals.) Pp. xi+164. (London: Crosby Lockwood and Son, 1923.) 7*s*. 6*d*. net.

THERE are scarcely any books which give an accurate account of the progress that has been made in recent years in applying electric currents to horology. The explanations given in this work are confined mainly to the essential parts of the mechanism and the electrical and mechanical principles which they illustrate. Inventors of electric clocks who, as a rule, have only a hazy knowledge of what has been done previously, will find this book helpful.

The Phase Rule and the Study of Heterogeneous Equilibria: an Introductory Study. By Prof. A. C. D. Rivett. Pp. 204. (Oxford: Clarendon Press; London: Oxford University Press, 1923.) 10*s*. 6*d*. net.

PROF. RIVETT'S little book on the Phase Rule deals mainly with theory, the various types of equilibrium being set out under the headings of one, two, three and four-component systems. It is a useful type of book for a worker who wishes to make use of the Phase Rule in his own work, although less attractive to a general reader than a book dealing mainly with examples.

Letters to the Editor.

[*The Editor does not hold himself responsible for opinions expressed by his correspondents. Neither can he undertake to return, nor to correspond with the writers of, rejected manuscripts intended for this or any other part of* NATURE. *No notice is taken of anonymous communications.*]

Breeding Experiments on the Inheritance of Acquired Characters.

[AT the request of the Editor of NATURE, and of Dr. Kammerer, I have translated this letter from the original German into English. Dr. Kammerer has also sent me the typewritten script of a reply to Mr. Cunningham, but in an accompanying letter he tells me that he considers it superfluous to publish this now, as he is quite satisfied with the reply which I made to Mr. Cunningham in my letter to NATURE published on June 23. E. W. MACBRIDE.]

To begin with, may I remark that I have not seen Mr. Bateson's first criticisms of my work (NATURE, July 3, 1919, p. 344) which he cites in the course of his recent letter. Whilst I was in England, my colleagues informed me of the contents of Mr. Bateson's letter of 1919, but I had unfortunately no opportunity of referring to this letter myself. I regret this all the more, since if what I had been informed of its contents was actually in the letter, it would not have been possible for me to enter into any discussion of the subject with Mr. Bateson himself. I must therefore for the present confine myself to his most recent letter (NATURE, June 2, p. 738) and the remarks which he made on the discussion which followed my lecture to the Linnean Society,[1] in which he expressly apologised to me in case I had considered his previous attacks too rude.

It is indeed remarkable that Mr. Bateson on that occasion (May 10) did not produce a single one of the many objections which are contained in his printed letter of June 2. The general impression which I gained at the meeting was that he could not think of any further objection to raise. The "vague diagrams" which he complained of appear not to be derived from my original paper (1909, *Archiv für Ent. Mech.*, vol. 28, Plate 16, Figs. 25 and 26), but—if I am not mistaken—from Plate ("Selektionsprinzip," 4th edition, p. 469, Fig. 95) in which my simple figures have been rather strongly altered and exaggerated.

Mr. Bateson must, therefore, have discovered by subsequent reflection all that during my demonstration and lecture he *did not* see. Otherwise it might have been possible for me to make him to see what he did not wish to see; I would certainly, for his benefit, have removed the Alytes specimen from the jar and he would have been able to view it—without obscuration by glass or background—from all sides under the lens: I treated it in this way during my stay in England for many colleagues (as, for example, for Mr. E. C. Boulenger and Sir Sidney Harmer).

On the occasion of the meeting of the Cambridge Natural History Society, I had at my disposal a Zeiss binocular microscope. Every unprejudiced observer could convince himself by its aid that the skin-area under discussion was of the nature of a nuptial pad—an area which according to Mr. Bateson was merely "a piece of thickened blackish-brown skin."

Numerous are the reasons which Mr. Bateson has given in order to be "absolved from basing broad conclusions on his testimony"; in a word, in order to deny the existence of the nuptial pads. First he questioned the existence of the pad; then he suggested it was merely a black patch of pigment; then, that it was present in only one specimen—consequently an accidental monstrosity; then he asserted that it was a shadow which appeared in the photograph; then, even that it had been produced by artificial retouching "in the wrong place," that is to say, on the outermost smallest finger, where in my untouched photograph (1919) some dirt had accidentally remained adhering. The microtome-sections of the pad-tissue, Mr. Bateson suggested, had been taken from another type of Anuran; then, since it appeared that homologous tissues of other species of Anura were of a different character, that these sections did not show genuine pad-tissue.

The most recent communication in which Mr. Bateson gives the impression which he received from the specimen which I demonstrated at the Linnean Society is capable of only two explanations, namely, either that Mr. Bateson is not an acute observer or that his theoretical views have affected his vision. In neither case can he escape the criticism that in describing "Dr. Kammerer's Alytes" he proceeded with a rashness unusual in a scientific man, especially when he makes slightly veiled accusations of "correcting Nature" against conscientious observers. We may now enumerate the points on which Mr. Bateson's "doubtful memory" has led him astray, namely:

(1) It is incorrect to say that my preparation of Alytes prevented a view of the dorsal aspect of the hand and only showed the palmar aspect—to make such a preparation it would have been necessary to fasten each finger flat against the substratum.

(2) It is incorrect to say that the black colour is restricted to the palmar aspect. (Why should Mr. Bateson assert this when he had not seen the dorsal aspect?) Actually the pads extend to the dorsal aspect and are therefore not "in the wrong place." It is curious to find Mr. Bateson prescribing to Nature the "right" place—Nature which has produced much more "astounding" and "curious creatures" (cf. Trichobatrachus) than my modest cultures of Alytes.

(3) It is incorrect to say "The right hand showed nothing special." On the inner side of the wrist-joint, on the insertion of the ball of the "thumb," there has been regenerated[2] a distinct dark pad—of course, not so large as that on the left hand.

(4) It is incorrect to say that the pad presents only "a dark uniform surface but no papillary or thorny structures." I send herewith an enlarged photograph in which "rugosities" can be seen on the edge of the pad with the naked eye. [I have verified this, but doubt very much whether the rugosities would appear in a print reproduced in NATURE.—E. W. M.] Unfortunately this photograph is taken from the palmar aspect; it was not foreseen that Mr. Bateson would criticise this, the most advantageous, position, in order to deny the presence of the pad on the dorsal surface, and to call in question the pad-nature of the whole structure. It is probable that the majority of my English colleagues have no idea how difficult it is to obtain a satisfactory photograph in our impoverished Austria. Of course, at the very first opportunity I shall have the upper side photographed; perhaps Mr. Bateson in his desire for truth will provide the necessary camera and photographic materials.

Dozens of scientific men have seen the pads and are now convinced; only Mr. Bateson has seen nothing. Unfamiliar as he is with this special department, he expects to see the same as can be seen in

[1] NATURE, May 12, 1923, p. 639, column 2, line 10, should read "macroscopic observation," not "microscopic."

[2] Dr. Kammerer stated at the meeting of the Linnean Society that the original pad on the right hand had been removed for the purpose of making microtome sections.—E. W. M.

Rana agilis. His assertion that the pads of *Alytes obstetricans* are not pads because they have a different appearance from those of *Rana agilis* is as unreasonable as it would be to maintain that *Alytes obstetricans* is not a Batrachian because it does not look like *Rana agilis.*

Lastly, a few words on the question of adaptation. In my lecture I avoided speaking of adaptation because this term involves a hypothetical and teleological element: I feared that to use it might lead to endless unfruitful discussion. Unfortunately, I was unable to prevent this; Mr. Cunningham discussed his own theory of adaptation in a way that had little to do with the facts which I had cited. I definitely declined to enter into this subject in my reply, simply because it is not usual for the discussion to wander so far from the subject of the lecture. So far as the nuptial pads are concerned, may I refresh Mr. Bateson's memory so far as to remind him that not only my Alytes but also other Batrachians, and especially the Discoglossidæ (to which Alytes belongs), have pads on places which never come into contact with the female? *Bombinator pachypus*, for example, develops pads on two or three toes of the *hind* foot (cf. Schreiber, "Herpetologia Europæa," 1912, p. 175). Are these "in the wrong place" or "retouched" by Nature?

I willingly admit that the traditional explanation of the pads, namely, that they are produced by friction with the skin of the female, may possibly be a fable: for that reason I have referred to this view with reserve and scepticism in my paper (1919, pp. 331, 339, 353). It is true that the spread of the thickening to regions of the skin which in the copulatory act do not undergo friction, is no valid ground for rejecting the theory. Mr. Bateson has doubtless himself observed that pressure thickenings and blisters often extend beyond the original zone of irritation. But it is by no means impossible, although of course not proved (Kammerer, 1919, p. 340), that life in water produces the pads; if this were so we should have a case of direct passive production but not of active adaptation. The correctness of my observations and their relevance to the theory of heredity, is not affected whichever of the explanations is adopted.

PAUL KAMMERER.

DR. BATESON, in a letter to NATURE of June 2, raises the very interesting point as to whether the appearances alleged to be "nuptial pads" in *Alytes obstetricans* are really such. Whatever their nature, they are undoubtedly organised structures; and if they should prove not to be "nuptial pads," they will have to be regarded as a new and arbitrary feature which has appeared after subjection to an experimentally altered environment for two or three generations, and which persists for at least a few generations after a return to normal conditions. In other words, it would seem that Dr. Kammerer has had success in an experiment which is almost analogous to those ancient researches in which was attempted the reproduction by hereditary means of a surgically impressed modification.

However, Dr. Kammerer has clearly stated that in his opinion the only feature of the experiment which in any way justifies such a view is that the excrescences in question are not dependent for their development on the presence of a testis, and in this differ from the nuptial pads of the better known Amphibia Anura.

Dr. Bateson points to two details which make "the appearance quite unlike that of any natural *Brunftschwielen*": first, that in Alytes there is a "dark uniform surface . . . without the dotting or stippling so obvious in true *Brunftschwielen*"; secondly, that their position does not correspond to that of the nuptial pads in *Rana agilis*.

Lataste's excellent drawings (*Ann. Sci. Nat.* (6), tom. 3, pl. 11, 1876) show that a uniform blackness of the outer layer of the pad is a characteristic feature of the Discoglossidæ (to which Alytes belongs) and distinguishes them from other Anura. The fully developed pads of *Bufo vulgaris* are also uniformly black, and I have recently found that when such full hypertrophy of the outer epithelium is inhibited, as occasionally happens from obscure causes, it may be induced by making the male maintain a sexual embrace for a week or two. The same effect may be produced in the summer condition of the pad, and I have found that the hypertrophy takes place even when the male maintains his tonic embrace on thin air.[1]

The pad of the Alytes "water-breed" also resembles that of the Discoglossid Bombinator in having a complete layer of black pigment in the cutis vera which would further contribute to the uniform dark appearance which Alytes so well and characteristically shows. Photographs show another interesting point. Very distinct connective-tissue papillæ are developed from the cutis vera in association with the epidermal spines. Such papillæ are but very slightly developed in the Discoglossidæ, though Lataste's picture of Discoglossus shows traces, whilst they are a characteristic feature of the pads of many other Batrachians.

The epidermal spines are very obvious in the intact specimen, as I have repeatedly seen both with lens and binocular microscope, and as many others have witnessed in my presence. Of course, they are practically impossible to photograph on account of the glistening of a wet specimen, but a photograph at least makes clear what areas of skin are affected. These include nearly the whole of the palm, the radial surface of the inner metacarpal and part of the first phalangeal joint of the thumb, and more or less of the ventral and radial surfaces of the forearm, passing over the dorso-radial margin of the inner carpal tubercle. The Discoglossidæ are remarkable for the very various positions in which the histological features of *Brunftschwielen* may manifest themselves, on the chin, belly, thighs, toes of the feet even; in other words, they are not necessarily dependent on contact with the female for their development. Dr. H. Gadow has shown me his sketch of the nuptial pad in *Alytes cisternasii*, Bosca., where it is developed on the tip of the thumb, extending on the palmar surface. Even in the common toad I have frequently observed the nuptial rugosity extending on to the palmar surface of the inner carpal tubercle.

Questionable as it is to draw conclusions on anatomical points by analogy from other animals, it is even more unsafe to do so as regards their habits and postures; Alytes does not belong even to the same suborder as *Rana agilis*. De l'Isle (*Ann. Sci. Nat.* (6), tom. 3, p. 18), in his account of the cervical clasp of Alytes, says with regard to "les paumes," "les applique contre le cou de la femelle." Moreover, although he gives no definite description of the attitude of the hands during the inguinal clasp, he describes how, with the fingers interlaced, the two backwardly directed internal digits participate in the well-known chafing of the cloaca, which seems to me anatomically impossible if the hands are so much everted that the palms do not come in contact with the pubic region, the groins, or at least the thighs of the female.

Light-Quanta and Interference.

In a very important and stimulating paper on the scattering of X-rays by light elements (*Phys. Review*, May 1923), Prof. A. H. Compton suggests that a study of the problem of scattering by atoms with tightly bound electrons and by groups of atoms may shed some light upon the difficult question of the relation between interference and the quantum theory.

In an investigation of this kind it may be useful to keep in mind an important difference between an electron and a light-quantum, which depends on the fact that generally most of the electron's energy is unavailable, while the whole energy $h\nu$ of a light-quantum seems to be available. This indicates, of course, that a light-quantum is a simpler form of matter than an electron or proton.

Roughly speaking, a light-quantum possesses a large amount of available energy and a small momentum, while a moving electron generally possesses a small amount of available energy and a comparatively large momentum. As a rule, then, we cannot expect a free or lightly bound electron to absorb the whole energy of a light-quantum. It is indeed possible, according to the theory of Compton and Debye, for an electron which encounters a light-quantum $h\nu$ to move away with a kinetic energy equal to $h\nu$ if the electron has an initial kinetic energy nearly equal to $h\nu$, but this case is not of much physical interest. When, however, an electron is tightly bound to an atom, so that some of the energy of an impinging quantum may be transformed into potential energy, there is a possibility that the whole energy of the quantum may be absorbed in a single impact.

If we admit that the energy of a quantum can be absorbed bit by bit, it does not follow that the type of absorption considered by Compton is the only one which can occur. Let us suppose that a quantum $h\nu$ after encountering an atom is transformed into a quantum $h(\nu - d\nu)$ travelling in the same direction as the original quantum. Assuming that the atom (of mass m) acquires the energy $hd\nu$ and momentum $hd\nu/c$ lost by the quantum, the centre of mass of the atom may be supposed to move forward with velocity $hd\nu/mc$ and a kinetic energy $h^2(d\nu)^2/2mc^2$, which is generally negligibly small in comparison with $hd\nu$. The acquired energy $hd\nu$ may therefore be energy of small oscillations about a state of steady motion. To ascertain the nature of these oscillations we represent the incident quantum by a field of type

$$E_x = H_x = 0, \qquad E_y = H_z = \frac{\partial\Omega}{\partial y} f\left(t - \frac{x}{c}\right),$$

$$E_z = -H_y = \frac{\partial\Omega}{\partial z} f\left(t - \frac{x}{c}\right),$$

where $$f(t) = \int_0^{2\pi\nu} \cos(pt + \alpha)dp.$$

(See Nature, April 28, p. 567.)

The emergent quantum may be represented by a field of the same type with $\nu - d\nu$ instead of ν, while the field which is really effective in producing the oscillations is the difference of these two, and is of the same type with

$$f(t) = \int_{2\pi(\nu - d\nu)}^{2\pi\nu} \cos(pt + \alpha)dp.$$

When $d\nu$ is very small, this represents approximately a homogeneous train of waves of frequency ν. The small oscillations set up in the atom are thus specified approximately by a trigonometrical function of type $2\pi d\nu \cos(2\pi\nu t + \alpha)$ and are practically undamped and of frequency ν. The phenomenon of interference may, then, be quite compatible with quantum theory, for it may depend really on an interference of small oscillations produced in the atoms by the quanta. If a number of quanta in phase strike the same atom, the small oscillation may become large and eventually result in a quantum jump, but the growth of an oscillation may depend, of course, on the phenomenon of resonance.

Since we have endowed a quantum with a field, a single quantum may produce small oscillations in a large number of atoms in accordance with Compton's idea, and so a second difficulty in the theory of interference may not be so great as it seems at first sight.

A Mountain Mirage.

As part of a magnificent view from Ben More of Mull on July 13, my sister and I saw a striking mirage on the Coolins of Skye. To begin with, Skye and all the Highlands to the eastward of it were covered by a level sheet of white cloud, with the highest peaks just showing clear and sharp above it. Then, starting from the sea, this cloud gradually melted away, and revealed a magnificent prospect extending far past the Coolins into the mountains of Ross. But as the cloud first melted it left the Coolins strangely transformed, each of their jagged crests drawn up into a fantastic spire. In the course of a very few minutes this effect died away and the Coolins took on their natural outline.

This was about 6.30 p.m., summer time. Presumably the mirage had some connexion with the cloud sheet; at one stage of its absorption the sheet must have been represented by a refracting layer, which would be very nearly at our eye-level. The air was remarkably clear, not only to the north but also to seaward. For some time a long line of the Outer Hebrides, from about South Uist to Barra Head, was visible, pale but perfectly clear-cut.

Probable Aeolian Origin of Greywether Sandstone.

On reading Mr. C. Carus-Wilson's note (Nature, March 3, p. 292) referring to the long tubular holes seen in sarsen stones, which he says suggest "the work of marine annelids, anterior to the consolidation of the rock," it struck me that some important light may be thrown on this subject by observations made on this side of the globe. First of all one might suggest that if these were annelid burrows they would have an average diameter, and there seems to be no evidence that the greywether sandstone, with its once softer siliceous matrix, was of marine origin. In Australia we have a great extent of country along the coast and inland, covered with dune formation, and these deposits enclose enormous quantities of vegetation. Plants that are growing on or near these dune areas, sometimes under swampy conditions, are covered over with sand, which is being blown about the stems of such grasses, reeds, and shrubs so as to completely enclose them. When the dune rock, some of which dates back to the early Pleistocene, has consolidated, a fracture reveals tubular holes which might suggest worms, but from their positions, at all angles, as well as vertical, and from their varied diameter and outline, are easily traced back to plant origin.

From many years' observations upon our Australian dunes, I cannot help thinking that here we have a similar process going on, which obtained during the arid interludes of the Eocene in the south of England.

Evidence of cross-bedding, which is inseparable from this type of rock, would be easily lost, since the greywethers are secondarily silicified or "concretionary." From conversation with the late Prof. Rupert Jones, than whom I knew no keener observer, I gathered that he firmly believed in the rootlet and stem structure of these perforations (see *Geol. Mag.*, 1901, pp. 54-59 and 115-125). Another recorded instance of enclosed rootlets is given by Wm. Carruthers (*Geol. Mag.*, 1885, p. 361), who found in a weathered sarsen stone from Abury a root with rootlets, which he doubtfully ascribes to a palm, and in the position of growth.

It would be interesting to discover any positive evidence of cross-bedding in these white Tertiary sandstones. The Bagshot sands, by the way, both in Surrey and Kent, are often strikingly and steeply cross-bedded, and this, from a study of our dune rock in Victoria, points to aeolian formation rather than to marine current action. Barometric Pressure in High Latitudes.

I AM much obliged to Mr. L. C. W. Bonacina (NATURE, July 21, p. 100) for pointing out a clerical error in my statement concerning the winter and summer Arctic pressures. The correction gives greater emphasis to my contentions.

My point is that in the Arctic regions, even during the winter when the sun's light does not reach the area to any extent, the pressure is low, indicating a sufficiently warm stratosphere able more than to counterbalance the effect of the cold lower troposphere.

The lower troposphere over the polar areas is undoubtedly very cold, and this cold air often flows outwards from the poles for some distance. I am not aware that my views on this point are in conflict in any way with those of Dr. G. C. Simpson, Prof. Mohn, or Prof. Bjerknes, except on very minor points. What I have attempted to explain is not why these northerly Arctic winds exist, but rather why they do not blow from the poles to the equator. The real difficulty, to my mind, is to account for the westerly poleward winds of middle latitudes.

Mr. Bonacina says "there must, on the average, be a relatively high surface pressure about the poles." But all the charts show a relatively low pressure. However, an outflow of cold air from the poles will occur if the density of the *lower* troposphere decreases with sufficient rapidity as we move towards lower latitudes; and this is what actually often occurs, for the temperature rises as we move from the poles.

Phototropic Compounds of Mercury.

IN NATURE of June 9, p. 775, Messrs. Venkataramaiah and Rao describe "A New Phototropic Compound of Mercury" of the composition $Hg\begin{matrix}\diagup HS\\ \diagdown CNS\end{matrix}$, which they regard as "the most phototropic compound as yet known"; or that this compound shows appreciable change in colour on exposure to light in less time than that required by any other known phototropic compound. In 1917, while working in the College of Science, Calcutta, in an attempt to prepare $(SHgI)_2$, described by Ray (Trans. Chem. Soc., 111, 109), without using any organic compound, I obtained $2HgS.HgI_2$, which showed phototropy to a remarkable degree. The orange yellow powder turned black very quickly on exposure to sunlight, but only gradually in diffused daylight. On keeping the black powder in the dark, the reverse change took place. At room temperature, it took several hours to recover, but at higher temperatures the change of colour was quicker; at about 85° C., for example, only a few seconds. Both varieties had the same chemical composition. This substance was exhibited before the Indian Science Convention of that year, and a preliminary note was published in the Report of the Indian Association for the Cultivation of Science, 1917. Since then I have found that phototropy is exhibited more or less by all the complex sulphides of mercury of the general formula $HgS.HgX_2$ or $2HgS.HgX_2$, where X is a halogen or a monovalent acid radicle, including CNS, of which $2HgS.HgI_2$ is the most sensitive.

The sensitiveness to light depends to some extent, as might be expected, on the nature and area of the surface exposed. I have found that paper coated with an emulsion of $2HgS.HgI_2$ in gelatin is much more sensitive to light than the powder. In fact, it turns black more quickly on exposure to light than the ordinary gelatino-chloride paper used in photography. But it is very curious that in this case the reverse change of colour does not take place on keeping in the dark or heating. Evidently the gelatin somehow prevents the reversal. A detailed report on these inorganic phototropic compounds will be published in due course. M. L. DEY.

Melanism in the Lepidoptera and its Possible Induction.

BELIEVING that light can be thrown on some of the problems of evolution by an experimental investigation of the development of melanism in lepidoptera, we have been studying the influence of the food plants growing in critical areas, and also of inorganic substances likely to occur in or on the plants of such regions, on races of moths imported from non-melanic districts. Our cultures have been reared at two centres; some at Birtley (Durham), an area producing a very large number of melanic species, and others at Hexham (Northumberland), where melanism is much less prevalent, although not absent. The work is not finished, but certain facts seem worth publishing at once, particularly in view of the recent controversy as to the value of Kammerer's experiments.

We began with Kentish races of *Tephrosia crepuscularia* Hb., and Kent and Hampshire strains of *T. bistortata* Goeze, rearing them on hawthorn gathered by the roadside at Birtley, and in the third generation of *T. crepuscularia*, a species in which we have proved melanism to be a Mendelian dominant, obtained one black female in a brood of 23 insects. *T. bistortata*, on the other hand, showed no change in the fourth generation, at which stage the eggs from one pairing were sent to Hexham and others reared at Birtley, where in the next (fifth) generation one black female was obtained from about 90 pupæ. The eggs at Hexham, cousins to those at Birtley, were divided into four batches, the larvæ in one case being fed on local hawthorn and in the others on hawthorn impregnated with a metallic salt. In each culture one or two black moths appeared, the broods averaging two dozen in number.

In 1918 pupæ of *Selenia bilunaria* Esp. were obtained from Kent, and broods resulting from these reared at Birtley on hawthorn from the roadside. In the following year the spring brood, the second lot fed at Birtley, gave a batch of moths containing a large number of typical insects, several melanochroic forms together with two insects uniformly leaden black. A black female was paired with an unrelated typical male, and F_1 and F_2 generations secured; the results suggested that the melanism was recessive, as in the allied moth *Ennomos quercinaria* Hufn. Another batch of ova was obtained from a typical wild Abbot's Wood (Sussex) female in July 1921, and after two generations had been reared at Birtley, eggs were sent to Hexham. Some of the larvæ were fed on prepared hawthorn, the salts used being lead nitrate and manganese sulphate. The moths emerging in the spring of 1923 showed no particular variation, but were paired, and the treatment continued. The summer brood proved extremely interesting. The controls began to show the effects of inbreeding, only 12 moths resulting from 60 eggs, and 3 of these were dwarfs; but there was no melanism. From one batch of larvæ fed on hawthorn containing lead nitrate 12 males and 15 females were bred; all were of normal size, but 1 male was practically black. Another such batch gave 20 males and 11 females, 1 male again being melanic. A fourth section, reared on hawthorn charged with a manganese salt, yielded 11 males and 9 females; these displayed both melanism and melanochroism, 6 males and 2 females being of the black type, whilst insects absolutely typical were practically absent. All of these melanic forms are fairly uniform in colour, showing no markings except an almost white line such as is so common a feature of melanic lepidoptera.

In partnership with Mrs. Garrett, one of us recently directed attention in these columns to the effect of lead on *Smerinthus ocellatus*, and the same workers have now tried it with *Amorpha populi*, the eggs originating with a wild Hexham female. The larvæ again fed up more rapidly, but whereas the *S. ocellatus* pupæ were heavier, those of *A. populi* were about 15 per cent. lighter than those of the controls. They were perfectly healthy, however, and moths were obtained from every pupa save one. Though there was no definite melanism, there was a tendency towards it, the colours being more intense and the markings more clearly defined; the difference was sufficiently great to enable one of us, who had not seen the moths before, to sort them correctly without any clue as to their history.

As the investigation is being continued, and the study of the inheritance of the induced melanism well in hand, we content ourselves with a mere statement of the facts; next summer we hope to be able to publish fuller details.

The Reported Meteorite at Quetta.

The issue of Nature of May 26, p. 704, contains a short communication from my Department correcting a report concerning the fall of a meteorite at Quetta. Further inquiries make it desirable that the opinion in that letter should be modified. Though no traces of a meteorite can be identified in the material collected, it does not necessarily follow that a meteorite did not fall.

During a storm at Quetta on the afternoon of January 25 last, a large ball of fire is reported to have fallen and struck a stack of baled *bhoosa* (chopped straw) in the Military Grass Farm Stack-yard. The stack, composed of 12,800 bales, was for the most part consumed by fire, and amongst the ashes were found some three tons of a hard dark stone. Portions of this stone were forwarded to the laboratory of the Geological Survey and found to consist of slag, parts of which showed a ropy structure and slightly scoriaceous texture. As we were informed that no one had actually seen the fireball strike the stack, it was at first thought that the latter was ignited by a simple flash of lightning. Later information, however, makes it possible that a meteorite did actually fall into the *bhoosa* stack. Not only was the "ball of fire" witnessed by several people, but the men who were set to work on top of the stack extinguishing the fire immediately after its outbreak reported a hole in the stack 18 inches wide, and their observation was confirmed by Conductor Trewhella, who noticed that the hole led towards the centre of the stack.

The possible sequence of events may be reconstructed as follows: The *bhoosa* was struck and ignited either by a meteorite which burned its way to the base of the stack, or by a simple flash of lightning. The intense heat fused the iron bands binding the bales of *bhoosa*, and this iron combined with the silica in the *bhoosa* itself or with any mud roofing which may have been present. Mr. A. J. Gibson, of the Punjab Forest Service, has reminded me that the tissues of the Gramineæ contain an unusually large percentage of silica, and 12,000 bales would probably supply sufficient to form most of the three tons of slag, consisting of silicate of iron, free iron, and impurities.

The meteorite, if there were one, was itself probably of iron, and would have mixed with and become part of the fused slag. Unmelted fragments of the iron bands of the *bhoosa* bales were found in the cooler portions of the melt. In such circumstances it is of course impossible to identify any remains of a meteorite in the slag.

Scientific Names of Greek Derivation.

In Nature for July 7, p. 10, Prof. Cole criticises "American authors" for using the term dinosaur, instead of clinging as he does to "deinosaur." In a previous number of Nature (July 1, 1922, p. 21) the reviewer of an article on the Deinodontidæ takes the authors to task for not using "what is now considered the more correct rendering of the Greek, as Dinodontidæ." What can a poor American author do to be saved?

In fact, the usual custom among American and Canadian palæontologists has been to follow the rules of the International Code for names of genera and families, and otherwise adhere to the original spelling of scientific names, although some of us have had sufficient classical training to dislike having to use badly composed or wrongly transliterated names. Dinosauria was Owen's spelling of the word and Deinodontidæ is formed according to the rule from the radical of Leidy's genus as originally proposed.

While the rules and recommendations of the Code are a sufficient guide for future coining of names, its retroactive applications are not altogether clear, and it does not provide any definite guide for the spelling of the larger group names or other scientific terminology. Is there any scientific dictionary to which one could refer as internationally authoritative? Or could the matter be taken up by the next international congresses of zoology and geology?

Hardness Tests.

EVERY one has a general idea of what is meant by hardness—that the diamond is harder than steel, and steel harder than copper. The workman judges of hardness as the resistance of a material to the action of his cutting-tools or files. But there is as yet no rational definition of hardness. A property connected with hardness is resistance to abrasion or wear. As Sir Robert Hadfield has said, rails are demanded which will not wear out quickly and tyres which will not need renewing every few months. It was entirely for these reasons that modern qualities of steel were produced. To some extent hardness is opposed to ductility or toughness. Very hard materials are generally brittle. The engineer requires a material in which hardness is obtained without too great a sacrifice of toughness.

The earliest scale of hardness is that proposed by Moh. He selected ten minerals arranged in order such that each would scratch the one next below it in order and be scratched by the one above it in order. On this scale talc has a hardness 1 and diamond a hardness 10; iron has a hardness of 4·5. But the scale is qualitative only and arbitrary. Prof. Turner has used a balanced lever turning on a knife-edge. The free end carries a diamond. The surface to be tested is polished. The hardness is taken to be the weight in grams on the diamond necessary to produce a definite scratch. The method is useful, but there are practical difficulties in applying it. Recently Mr. Hankins, at the National Physical Laboratory, has modified this test. He uses a diamond shaped so as to produce an indentation furrow rather than a scratch.

The diamond is loaded with weights and drawn over the surface to be tested. The widths of the scratches with different weights is measured, and it is found that the square of the widths plotted against the weights fall on a straight line passing nearly through the origin. Hence Mr. Hankins takes as the hardness number the quantity

$$k=\frac{P-p}{w^2-q},$$

where P is the load on the diamond, w the width of scratch, and p and q small constants not depending on the material tested.

Various investigators have used an indentation method for determining hardness. Such a test is very suitable for ductile metals, but how far it is applicable to brittle materials is uncertain, though this is not of practical importance. The indenting tool has been a knife-edge, ball, cone, or pyramid.

In 1895 and 1900 Lieutenant-Colonel Martel communicated two very interesting papers to the Paris Congress on Testing Materials. He used chiefly a falling monkey with various forms of indenting points and various heights of fall. He concluded that (1) for a given material the work of indentation is proportional to the volume of the indentation and independent (within limits) of the form of indenting tool; (2) that the pressure causing indentation is at each instant proportional to the area of the indentation normal to the pressure. If V is the volume of the indentation, P the weight of the monkey, and h the height of fall, then Martel's hardness number is

$$D=\frac{Ph}{V}$$

in kilogram-millimetre units.

About 1900 Brinell introduced the indentation test, which has been most widely used. A very hard steel ball 10 mm. in diameter indents the material by a gradually applied load of 3000 kilograms, which rests on the ball for some seconds until the indentation is complete. The radius of the indentation is measured by a microscope. If P is the load, a is the radius of the indentation, and r the radius of the ball, then Brinell's hardness number is

$$H=\frac{P}{2\pi r(r-\sqrt{r^2-a^2})}.$$

The quantity in the denominator is the spherical surface of the indentation; and the units are kilograms and millimetres. In practice it is necessary to use a smaller load for soft materials and sometimes to use a smaller ball. Then the hardness number obtained is not the same unless the load P_1 and the ball radius r_1 satisfy the condition

$$\frac{P}{r^2}=\frac{P_1}{r_1{}^2}.$$

This is Meyer's law confirmed by Mr. Batson, of the National Physical Laboratory. If the law is complied with the indentations are geometrically similar.

Prof. Ludwik uses a right-angled cone instead of a ball, so that the radius and depth of the indentation are equal and the indentations for different loads are similar. He also takes the hardness number to be the load divided by the conical area of the indentation.

Prof. Föppl placed two cylinders of the material to be tested at right angles and pressed them together in a testing machine. The pressure per unit of flattened surface is taken as the hardness number. Prof. Henderson, of Greenwich, has introduced a similar test, the material being in the form of square prisms.

For ordinary materials of construction, Brinell's test has proved most useful. It rather fails for very hard materials from the smallness of the indentation and the distortion of the ball, and efforts have been made to find another test or to revive the scratch test for such cases.

A new instrument which appears to be very sensitive has been introduced recently by Messrs. E. G. Herbert, Ltd., of Manchester (see NATURE, April 28, p. 583). This consists of an arched pendulum weighing 2 or 4 kilograms. At its centre is a ball 1 mm. diameter of ruby or steel. By adjusting screws the centre of gravity of the instrument can be made to coincide with the centre of the ball. A weight over the ball can be adjusted to lower the centre of gravity of the instrument to 0·1 mm. below the centre of the ball when the time of swing on a very hard surface is 10 sec. A level tube over the ball is graduated from zero at one end to 100 at the other. Two scales of hardness are

proposed: (1) Inclined to zero and left, the reading of the level bubble at the end of the first swing is taken as the hardness number. The softer the material, when the indentation due to the weight of the instrument is deep, the shorter is the swing. (2) The time period of an oscillation is another measure of hardness. The time in making ten swings is taken as the hardness number. Thus the time of ten swings on glass is 100 sec., on hardened steel 50 to 85 sec., on soft steel 20 to 40 sec., on lead 3 sec. The pendulum is set in oscillation through a small arc by the touch of a feather. The sensitiveness of the instrument is very great, and it gives definite indications with the hardest materials.

Dr. Stanton has designed an ingenious instrument in which the deformation of a very hard ball used in the indentation test is substituted for the deformation of the material. This gives a much opener scale for hard materials. But the instrument is one for laboratory rather than workshop use.

W. C. U.

Structural Colours in Feathers.[1]

By Prof. WILDER D. BANCROFT.

IN pigment colour we have absorption of light due to the molecular structure of the substance under observation. We speak of structural colours when the observed colour is due to, or is modified strongly by, the physical structure. Typical cases of structural colour are observed with prisms, diffraction gratings, thin films, and turbid media. In the case of feathers we find that the blacks, reds, oranges, yellows, and browns are pigment colours, but that the ordinary blues and greens are not blue and green by transmitted light, and that the so-called metallic or iridescent colours, such as those of the peacock, are structural colours.

Biologists have often talked of prismatic or diffraction colours, apparently because those were the only structural colours that they knew about; but they have never tried to show that any arrangement of prisms or gratings would give the actual colours observed. Since prisms and gratings give no colour in a uniform diffused light, it is only necessary to look at a feather on the north side of a house, preferably on a grey day, and all prismatic or grating colours will disappear. Nothing of the sort happens, except to an almost negligible extent, with some moths.

If we have a turbid medium with fine particles, the scattered light is predominantly blue—Tyndall blue—and the transmitted light is reddish. Familiar examples of this are skimmed milk and cigarette smoke. The blue of the sky is also a Tyndall blue, the scattering being due in large part, however, to the molecules of nitrogen and oxygen, as was shown by the late Lord Rayleigh. In feathers of the non-iridescent type, Haecker showed that we have myriads of tiny bubbles in the horn which scatter the light, and a black backing which cuts off all transmitted light. On filling the bubbles with a liquid having approximately the same index of refraction as the horn, the scattering ceases and the blue colour with it. On putting in carbon bisulphide, which has a much higher index of refraction than the horn, the blue reappears because we again have a turbid medium. The blue of the feathers can be reproduced wonderfully by heating a hard glass tube until it begins to devitrify. The myriads of small crystals which are formed scatter the light, and a beautiful blue is obtained if the inside of the tube is coated with a black varnish to eliminate transmitted light.

In almost all cases of non-iridescent green feathers, there is no green pigment and the effect is due to the superposing of a yellow pigment on a structural blue. This can be shown in a number of ways. If we take a green feather and boil it long enough in alcohol, the yellow pigment dissolves and the feather turns blue. If we expose the green feather long enough to an intense light, the yellow pigment bleaches and the feather becomes blue. If we scrape the surface of the feather with a sharp knife, we can peel off a layer of yellow horn and the feather again turns blue.

The metallic or iridescent colours, such as those of the peacock, were considered by Rayleigh to be the interference colours of thin films like those observed with oil films on the streets, while Michelson believed that they were so-called surface colours from solid pigments. Fuchsine gives a yellow-green surface colour quite different from the magenta colour by transmitted light. Our experiments have satisfied us that Rayleigh was right and Michelson wrong. There are no bright-coloured pigments in peacocks' feathers or in any feathers of that type. In the case of the peacocks there are triple films, but this is not so in the neck feathers of the pigeon.

Nobody has ever extracted any bright-coloured pigment from any iridescent feather, and we have confirmed this, using a large number of organic solvents. The change of colour with the angle of incidence is what it should be for thin films, while magenta shows practically no change of colour with changing angle of incidence if one does not use polarised light. If one swells the feather by exposing it to phenol vapour, the change of colour is what one would predict from a thickening of the film. If one destroys the dark pigment, the colour disappears almost completely, though it can still be seen at certain angles. It can be brought back by staining the feather with a dark pigment. In the white pigeon, the iridescence of the neck feathers is very difficult to see, but it can be brought out vividly by staining the feather. Unfortunately the physical structure of the tail feathers of the white peacock is quite different from that of the ordinary peacock, and consequently staining does not develop brilliant colours.

The average thickness of the films in the iridescent feathers is about 0·5 μ or 1/50,000 inch.

[1] Synopsis of a lecture delivered at University College, London, on June 1, at the University of Aberdeen on June 7, and before the Manchester Literary and Philosophical Society on July 19.

Obituary.

Prof. C. Niven, F.R.S.

PROF. CHARLES NIVEN was born in September 1845, and was one of four brothers who achieved the distinction of being wranglers. He entered the University of Aberdeen as a student in 1859, graduated there with first class honours in mathematics and natural philosophy. In 1863 he proceeded to Trinity College, Cambridge, and in 1867 was senior wrangler. In the same year he was elected a fellow of Trinity College and was appointed professor of mathematics at Cork.

It was during the tenure of the professorship at Cork that the greater part of Prof. Niven's contributions to mathematical and physical science was published. Between 1868 and 1880 he produced thirteen papers on various subjects. His first paper, on the application of Lagrange's equations to the solution of questions of impact, was published in the *Messenger of Mathematics* in 1868, and, although the method is implicitly involved in Lagrange's general dynamical scheme, its effectiveness in dealing with problems of impulsive motions had previously not been adequately appreciated. This paper was followed by three papers on the wave surface, a paper on rotatory polarisation in isotropic media published in the *Quarterly Journal of Mathematics*, papers on the mathematical theory of elasticity in the Transactions of the Royal Society of Edinburgh, the *Quarterly Journal of Mathematics*, and the *Philosophical Magazine*, and a paper on a method of finding the parallax of double stars, and on the displacement of the lines in the spectrum of a planet, published in the Monthly Notices of the Royal Astronomical Society. In 1879 he communicated a paper on the conduction of heat in ellipsoids of revolution to the Royal Society, and in 1880 a paper on the induction of electric currents in infinite plates and spherical shells; both papers were published in the Philosophical Transactions. These two papers are the most outstanding of Prof. Niven's writings; the analytical skill exhibited in them is very great, and the results obtained are of importance.

In 1880 Prof. Niven was appointed to the chair of natural philosophy in the University of Aberdeen. The demands made on his time by the duties of his professorship and the development of the department appear to have prevented him from pursuing his researches farther. In 1917, however, he sent to the Admiralty a paper on the theory of the location of sound in water, which was of service in connexion with the campaign against submarines, but the paper was never published. His tenure of the chair at Aberdeen extended from 1880 to 1922, and during that time the department of natural philosophy increased greatly; in 1880 it was housed at King's College with very inadequate laboratory accommodation, but later it was removed to Marischal College, where new and extended accommodation was provided. The provision of the new laboratories and other rooms for the natural philosophy department at Marischal College was very largely due to Prof. Niven's initiative and energy, and their successful completion added greatly to the efficiency of the department. When natural philosophy was taught at King's College, only a small number of the students obtained any training in experimental work; with the extended accommodation it became possible to give experimental training to a larger number of students and to a greater extent. Additional lecture courses for students proceeding to an honours degree were also instituted.

In March 1922, Prof. Niven developed a serious illness from which he never fully recovered. He retired from the professorship at the end of September 1922, and his many friends hoped that he might enjoy a period of well-earned leisure, but after a few months free from work he died on May 11.

Mr. E. J. Banfield

THE *Melbourne Argus* announces the death, in May or June last, of Mr. E. J. Banfield, at the age of seventy-one. Mr. Banfield was born in Liverpool on September 4, 1852, and was the son of Mr. J. W. Banfield, of Ararat, Victoria. After having been occupied for some years as a journalist, he retired in 1897, with his wife, to Dunk Island, in lat. 17° 55′ S., between the Great Barrier Reef and the Queensland coast. Here he lived the life of a recluse, occupied in cultivating tropical produce, and in observing Nature, but he found time to describe his experiences in three books, "Confessions of a Beachcomber" (1908), "My Tropic Isle" (1911), and "Tropic Days" (1918).

The "Confessions of a Beachcomber" gives an attractive picture of Mr. Banfield's life on Dunk Island. It describes something of his success in adapting himself to his novel surroundings, alone with his wife except for a few natives, and it reveals him as a man of lovable nature, with a pleasant sense of humour, and as an acute observer of Nature. The book is full of the sunshine and luxuriance of the tropics. In vivid word-pictures it describes the birds which visit some gorgeous tree to feed on its honey or its fruit, the productiveness of the banana or the papaw, the habits of stick-insects or leaf-rolling ants, of dugongs, turtles, and sucking-fish, and many more of the charms of the tropics. Wherever Mr. Banfield records his observations he has something instructive to say; and in many cases his narrative is as entertaining as truthful. He tells us that his retirement was prompted by his wish to put into practical operation his regard for the welfare of bird and plant life. "Man destroys birds for sport, or in mere wantonness, and the increasing myriads of insect hosts lay such toll upon his crops and the fruit of the earth which by the exercise of high intelligence and noble perseverance he has improved and made plentiful, that the national loss is to be counted by hundreds of thousands."

Under Mr. Banfield's rule Dunk Island became a sanctuary for birds, many of which became bold and familiar. He did not hesitate to incur financial losses in order to remain true to his principles. A promising attempt at bee-keeping was relinquished because of the depredations of two species of bee-eating birds, which he would not interfere with in order to save his bees. His death, which took place on the island, was reported by a passing steamer, to which his wife had signalled for assistance. His writings are well worth the attention of zoologists, botanists, and ethnologists, who will find them to contain much that is illuminating and interesting.

S. F. H.

Current Topics and Events.

THE text of the twelfth Huxley Memorial Lecture, delivered recently by Sir Arthur Keith, is published supplementarily to this issue. Its title, "The Adaptational Machinery concerned in the Evolution of Man's Body," admirably defines the greatest of present biological problems, "infinite in extent and complexity," and still affording scope for "many centuries of labour." Such phrases measure the magnitude of Darwin's influence, exerted steadily for over sixty years. The Huxley lecturer, speaking from a vast knowledge of evolutionary biology, says that we know of no means by which the machinery of mechanical adaptation can be altered from without. With Huxley, he believes that the government which rules within the body of the embryo proceeds along its way altogether uninfluenced by occurrences or experiences which affect the body or brain of the parent. The machinery of adaptation has its "predetermined line" of action. We may carp at the word; but Huxley's meaning seems clear enough: he described a sequence in a natural order, not a consequence of a supernatural order. How far we have advanced along the thorny path which the great Darwinians mapped out for us may be judged fairly from the address itself. The question of use-inheritance is crucial; and while every failure to demonstrate its occurrence serves only to establish the Darwinian theory more firmly, there are those who still hope to find in the intricacies of the problem a door of escape from the position assumed by Darwin and Huxley and, we believe, the best and most philosophical workers in biology to-day. Man, even scientific man, does not seem altogether willing to assume his rightful place in the Universe; albeit the place which Darwinism assigns to him is fundamentally securer and philosophically grander than any other which individual or collective wit has designed. We are still far from plumbing the depth of wonder of the Universe of which we are a part, in which we "live, move, and have our being," and the "many centuries" of Sir Arthur Keith that separate us from that aim is a phrase that is good only because it does not bring imagination to a halt. This aspect of the Darwinian theory is still not widely apprehended; none of the natural sciences comes so near to intriguing the personal prejudices of its votaries as biology; but as potent to confuse present work and thought is that sterilising influence of great ideas which, while they liberalise for a time, do so spasmodically. Many workers, all unconsciously, turn from Darwinism because it does for them not too little but too much. Forty, thirty, and even twenty years ago, comparative anatomy and embryology pressed forward irresistibly with Darwinian enthusiasm. During the "many centuries" ahead the present reaction will probably have less significance than appears now; but, for the clarification of present work, Sir Arthur Keith's advocacy is timely.

IN a lecture entitled "Charles Darwin, 1809–1882" delivered to the teachers of the London County Council on March 21, and now published (London: Cambridge University Press, 2*s*. 6*d*. net), Prof. Karl Pearson has brought out with great clearness the importance of the successive revolutions in thought caused by modern discoveries in astronomy, geology, and anthropology, unified as the two latter are by the crowning achievement of Darwin. Prof. Pearson is no doubt justified in attributing the comparatively slow progress of scientific investigation before Darwin to the fact that even among scientific men the date of 4004 B.C. was commonly accepted for the creation of the universe. Many excuses may be offered for this obsession, but it is fair to remember that the date represents only the computation by an Irish Archbishop of the figures given in the existing text of Genesis, and can scarcely be spoken of as having been "fixed by the Church." Perhaps Prof. Pearson is a little too much apt to revive the memory of "old forgotten far-off things, and battles long ago." However, there can be no doubt of the magnitude of the revolution effected by Darwin, a revolution which has made itself felt in every department of human thought. In view of recent occurrences in America, it can scarcely be considered unnecessary to insist once more on the indisputable fact that the doctrine of evolution, thanks to Darwin, is now as thoroughly established as any of the great generalisations of science. Prof. Pearson does well also to emphasise the admirable personal qualities of Darwin.

ABOUT twenty years ago (see NATURE, October 20, 1904, p. 602, and December 15, 1904, p. 156) the performances in Berlin of an intelligent horse—"Clever Hans"—were tested by a committee of psychological experts. The conclusion arrived at was that the performances of the animal, like those of the horse "Mahomet," exhibited in London several years previously, and of performing animals generally, depended chiefly upon observations of movements of the trainer. An experiment carried out by the Marconi Company in connexion with the Zoological Society, at Regent's Park on August 9, supports this conclusion as to the perceptual character of animal thought. The trainer of an Indian elephant at the Society's Gardens spoke to the animal from the British Broadcasting Company's studio, and his voice was distinctly heard in a loud-speaker arranged against the elephant-house. Four orders were given by the trainer, and, though they are always obeyed immediately when he is near, the elephant took no notice of them clearly uttered by the trumpet attached to the wireless receiver. It is possible, of course, that though the words could be heard easily by the people present at the experiment and listening for them, the absence of the trainer deprived the elephant of the associative relation between sound and action. This might be tested by connecting an electrophone with a gramophone record of the trainer's orders, the trainer himself being present but not actually speaking. We should then learn whether an elephant can recognise "His Master's Voice," like the Scotch terrier of the well-known advertisement of gramophones.

FOR the protection of inventions, justification of the patent system is based upon the demands of natural justice and upon economic grounds of pure expediency, a justification which has been recognised in all countries. Similarly for the protection of scientific ideas which are not inventions, justice demands a measure of protection even if expediency speaks with a voice less certain. From time to time, therefore, the cry is raised for protection to be accorded to such important discoveries as do not come within the category of inventions for which patents are obtainable; and now the matter is raised again, this time by the League of Nations. Thus the *Times* for July 30 informs us that the Intellectual Co-operation Commission of the League has decided to submit to the Council and to the Assembly a draft convention for the protection of scientific discoveries. In submitting the draft, the Commission is asking the Governments to establish for scientific discoveries "a copyright similar to that granted for literary and artistic work." What exactly is contemplated by the proposal is far from clear, neither the general idea nor the details having come to hand. If, however, the proposal deals only with the literary expression of a discovery, as might be inferred from the Press notice, it is difficult to see in what way the author of the scientific discovery would in any manner receive benefit. A discovery once published may be expressed in many different ways, such that no one of them need infringe copyright in the others. If the proposal is nothing more, the addition then to the legal systems of nations that it will make will be virtually nil. If, however, it submits a scheme whereby the discoverer of a natural principle or law of world-wide utility may receive a reward commensurate with the importance of the discovery, it is to be welcomed on all hands. Even if the proposal should be found to concern itself only with the literary expression of a discovery, it may yet serve a useful purpose, since it may result in directing public attention once again to the callous neglect of the interests of those to whom the world in the past has been so vastly indebted.

A WEEK of great interest has just ended at Oxford—one of real importance and significance. The seventh International Congress of Psychology has just concluded its meeting there, the last one having been held in Geneva in 1909. For the first time since the War, psychologists from all parts of the world assembled to discuss current problems of psychology. It is mainly due to its president, Dr. C. S. Myers, director of the National Institute of Industrial Psychology, that this result was achieved, and that the entire week passed off so amicably and instructively. The congress was limited to about two hundred members, and included representatives from Great Britain and Ireland, America, Austria, Belgium, Czechoslovakia, France, Germany, Holland, Hungary, Japan, Norway, Poland, Roumania, Spain, Sweden, and Switzerland. They were housed in New College and in Balliol and Manchester Colleges. There were numerous papers and discussions upon scientific and practical aspects of psychology, but no useful purpose would be served merely by recounting their titles. The proceedings opened on Thursday, July 26, with a meeting at which the president made a happy inaugural speech, and a letter was read from Lord Curzon, Chancellor of the University, welcoming the congress to Oxford. A reception was held the same evening in the gardens of New College. On the following afternoon Dr. and Mrs. William Brown entertained the members of the congress at a garden party in the gardens of Worcester College. On Sunday, July 29, the congress listened to a sermon given by Rev. Canon Barnes in the Cathedral, in which he alluded to the way in which science and religion could aid each other. In the afternoon a delightful excursion was made by river to Nuneham, where, thanks to the kindness of Lady Harcourt, the members of the congress were conducted by her and her daughters over the house and grounds. The congress ended in the evening of August 2 with a dinner at Christ Church. Psychologists may feel justly proud at having achieved so much, not only in advancing their own science, but also in promoting peace and goodwill amongst nations generally. About seventy members of the congress paid a visit to Cambridge on Thursday, visiting the Colleges and the Psychological Laboratory, which owes its existence to Dr. C. S. Myers, President of the Congress.

MR. H. SPENCER JONES, Chief Assistant at the Royal Observatory, Greenwich, has been appointed His Majesty's Astronomer at the Cape, in succession to the late Mr. S. S. Hough.

APPLICATIONS are invited from persons possessing an honours degree in electrical engineering or physics, and having experience of electrical research, preferably in the technique of alternating current measurements at high frequencies, for the post of a technical assistant at the Royal Aircraft Establishment, Farnborough. The applications should be addressed to the Superintendent.

THE following awards for the year 1923–24 have been made by the Salters' Institute of Industrial Chemistry, and approved by the Court of the Company. Fellowships are awarded to Mr. T. B. Philip, Imperial College of Science and Technology; Mr. W. G. Sedgwick, Armstrong College, Newcastle-on-Tyne; and Mr. D. T. A. Townend, Imperial College of Science and Technology. Fellowships are renewed to Mr. C. G. Harris, Jesus College, Oxford; and to Mr. J. H. Oliver, Imperial College of Science and Technology. Mr. W. Randerson, a fellow for 1922–1923, having been elected to an Albert Kahn travelling fellowship for the year 1923–24, is made an honorary fellow for the year.

THE Civil Service Commissioners announce that an open competitive examination for not fewer than 12 situations as probationary assistant engineer in the Engineer-in-Chief's Department of the General Post Office will be held in London, commencing on November 6 next. Limits of age: 20 and 25, with certain extensions. Regulations and form of application will be sent in response to requests by letter addressed to the Secretary, Civil Service Commission, Burlington Gardens, London, W.1.

The British Photographic Research Association, which was the first Research Association to be formed under the Department of Scientific and Industrial Research, completed its term of five years in May last. A thorough and searching investigation of the work accomplished has been made by the Department, which has also taken into consideration the researches which are either in progress or are contemplated, with the result that a further grant in aid for a period of years has been promised. Although the financial position of the photographic industry, which is comparatively a small one, is at present at a very low ebb, it is very satisfactory to note that the leaders of the industry are so convinced of the valuable work done by the Research Association, and of the good results which are likely to accrue, that it has been decided to carry on its operations. The Association has had to contend with considerable difficulties during its first five years, but, under the directorship of Dr. Slater Price, it has now a well-established reputation not only in this country, but also in Europe and America. A number of papers dealing with fundamental principles have been authorised for publication in the various scientific journals.

The Maidstone Museum has set a good example to other provincial institutions of this class by issuing a set of post-cards, published at $1\frac{1}{2}d.$ each, illustrating its prehistoric collections. These include a clay bowl attributed to the Bronze Age; palæoliths of the Chellean period; a group of eoliths; some neolithic flint implements—all found in the vicinity. The series also includes a set of good examples of Roman glass.

Our Astronomical Column.

D'Arrest's Comet.—MM. Dubiago and Lexin continue the search ephemeris of this comet (for Greenwich Noon): they use practically the same elements as those deduced by Mr. F. R. Cripps. There is still a prospect of finding the comet, as the greatest surface brightness is not attained until September 12; but the object is in considerable south declination in September and October.

The Shower of August Meteors.—Mr. W. F. Denning writes:—"The fine warm weather and absence of strong moonlight enabled these meteors to be well observed during the period from August 3-11.

"The display, however, up to the time of writing (August 12) has not been an abundant one, though a fair number of Perseids appeared each night, and the radiant showed its usual displacement to the east-north-east.

"Mr. J. P. M. Prentice, at Stowmarket, recorded the flights of 250 meteors up to August 9, and had recognised a number of the usual minor showers, including α Capricornids, δ and γ Aquarids, δ Cassiopeids, γ and θ Cygnids, Sagittids, ϵ Taurids, $\alpha-\beta$ Perseids, β Piscids, and Lacertids. Mr. Prentice saw a splendid Perseid fireball on August 9, 12h. 32m. G.M.T., with an estimated magnitude greater than that of the full moon. The streak lasted 23 seconds, and its colour was bright blue surrounded by bright red.

"Mr. A. King watched the shower from Lincolnshire on and after August 3, and saw a fair number of Perseids. At Bristol some observations were made on August 4-11, during which period the Perseids were only moderately active. The brightest meteor seen at Bristol was a Cygnid on August 11, 9.40 G.M.T. It was brighter than Jupiter, and traversed a short path from 289° + 66° to 289° + 72°; it left a white streak for a second, across δ Draconis."

Prof. R. Schorr's "Eigenbewegungs-Lexicon."—Prof. Schorr, director of Bergedorf Observatory, Hamburg, has just brought out a very useful work of reference in the form of a comprehensive catalogue of practically all the known proper-motions of stars. It is arranged in zones of declination, 1° wide, the designation of the stars being taken from the Durchmusterungs of Bonn, Cordoba, and the Cape. It is numbered by columns (two to a page) and there are 400 columns, each containing some fifty stars. Only one determination is given of each motion, presumably the best available; the authorities are given in each case. The centennial motion is given to two decimals of a second of time in right ascension, and one decimal of a second of arc in declination; a few stars are given to one figure less than this.

To diminish cost the work was typewritten, and then multiplied by a mechanical process, the result being perfectly clear and legible. The price is fixed at thirty Swiss francs.

Already a first supplement has appeared, containing 1739 stars; some of these, marked "!," are improved values for stars already in the Lexicon, but the majority are additional stars.

This is the second very useful work that Prof. Schorr has issued in a few months, his new reduction of Rümker's Hamburg Catalogue having lately appeared (Nature, April 28, p. 564).

The Free Pendulum.—Mr. F. Hope-Jones delivered a lecture on this subject to the British Horological Institute on April 19, and it has lately been issued as a pamphlet. He lays stress on giving the pendulum that we rely on as primary time-keeper as little work to do as possible; his three desiderata are: (1) the maintaining impulse must be given at the zero (lowest) position; (2) it must only be given occasionally; and (3) there must be no other interference with the pendulum.

Mr. Hope-Jones states that this problem has been solved, quite independently, by five men in the last twenty-five years: Mr. Rudd in 1898, Sir David Gill in 1904, Mr. Bartrum in 1913, Father O'Leary, S.J., during the War, and Mr. W. H. Shortt, who has been at work since 1911 on the matter, his clock being installed at Edinburgh Observatory early in 1922. The details of each of the five methods are briefly given, but the last is considered much the best. The fundamental pendulum, constructed of invar, is in an air-tight case, pressure 3·5 cm., kept at constant temperature. It receives its impulse every half-minute, at the lowest position; the remontoire is worked by the slave-clock, which is synchronised by a "hit or miss" action to within 0·01 second. Two diagrams of the changes of weekly rate in periods of three months are given; the range of weekly rate is 0·02 second per week. Prof. Sampson notes that the clock is superior to the Riefler instrument, though that is a very fine clock.

A clock with uniform rate is of great importance in fundamental astronomy for the removal of the small systematic errors in right ascension; they have been greatly reduced, but not wholly removed.

Research Items.

The Swiss National Park and its Mollusca.—First mooted in 1906, a National Park for Switzerland was finally established in January 1919. It is situate in the Lower Engadine, almost on the extreme eastern border of Switzerland, and abutting on the Italian frontier. It comprises an area of about 151·5 sq. km., and has been put in the charge of a Commission, which has wisely decided on a complete investigation of its fauna, flora, etc., a task which the Schweizerische Naturforschende Gesellschaft has undertaken to carry out. For the purposes of this survey, however, it has been resolved to include the territory to the north of the Park down to the banks of the Inn, as well as some to the east, so as to furnish a more satisfactory physical area to deal with as a whole. The first portion of this undertaking, the "Molluscan Fauna," by Ernst Bütikofer, has just been published by the Schweizerische Naturforschende Gesellschaft in Bd. lv. of their Denkschriften. If this be a fair sample the complete work will be well worthy of its authors. Following a general account of the characters of the eleven districts into which, for purposes of description, the district has been divided, come the molluscan fauna of each, a systematic description of the various species and varieties, with tables of their horizontal and vertical distribution, and an excellent bibliography. Close on eighty forms, if we include those in the appendix, are dealt with, and the photographs of shells are mostly particularly good.

Protozoa and Potato Mosaic.—As recently reported in Nature (July 21, p. 111), Ray Nelson has reported in America that a protozoal organism is associated with the phloem of potato plants affected by the disease known as mosaic, which is usually grouped among the "virus" diseases in which the causal organism is assumed to be ultra-microscopic. The July issue of *Phytopathology*, the journal issued by the American Phytopathological Society, contains no less than four brief papers, with which the names of seven investigators are associated, all pointing out that the structures described by Nelson are also present in the phloem of Solanaceous plants which are not affected by mosaic but, so far as can be determined, are perfectly healthy. There seems to be little doubt that Nelson has redescribed and photographed peculiar protoplasmic inclusions, present in the phloem of some Angiosperms but not in all, and which, as Irving W. Bailey and other writers point out in *Phytopathology*, are probably identical with the "slime bodies" described by Strasburger (in 1891) in the phloem of *Robinia Pseudacacia*. These "slime bodies" do not seem to be identical with nuclei, though they often are seen in contact with them. Ernst W. Schmidt, in his recent monograph upon the Angiosperm sieve-tubes (Jena, 1917), concluded that the nucleus was typically present in the Angiosperm sieve-tube. Possibly this recent American rediscovery of these other cytoplasmic inclusions will lead to a re-exploration of the cytology of the sieve-tube, a subject which would seem to be by no means exhausted.

Poplars.—Forestry Commission Bulletin No. 5, just issued by H.M. Stationery Office, price 1s. 6d., is a remarkably full account of the different poplars which are suitable for the production of timber on a commercial scale in Great Britain. The first chapter, due to Prof. A. Henry, is concerned with their botanical description, and is illustrated with two plates, showing clearly the distinctive characters of the twigs and leaves of the twelve important species and hybrids. The second chapter, by Mr. W. H. Guillebaud, who specially investigated the growth of poplars in the north of France, is devoted to silviculture, and discusses fully propagation, planting, thinning, pruning, rate of growth and yield. In the third chapter, Dr. J. W. Munro deals with injurious insects and Mr. W. E. Hiley with fungi and bacterial diseases. The last chapter, by Mr. W. H. Dallimore of Kew, is an admirable account of the character and uses of poplar wood, and should prove of great interest to both landowners and manufacturers, as the use of home-grown poplar timber is capable of great extension. For example, the wood of aspen is indispensable for the match industry, and has hitherto been mainly imported from Northern Russia. The recent plantation on a large scale of this tree in Argyllshire by Messrs. Bryant and May indicates that supplies of aspen timber from abroad at a reasonable price cannot in the future be depended upon.

Upper-Air Observations in North Russia.—A Professional Note, vol. 3, No. 32, carried out by Mr. W. H. Pick, has been published on the above by the Meteorological Office, Air Ministry. The observations are based upon pilot balloon ascents between February 25 and September 13, 1919, at three stations in north-west Russia. The stations are Murmansk, at the head of the Kola Creek, in latitude about 69° N., Archangel on the south-western coast of the White Sea, in latitude 64° 33′ N., and Lumbushi on the Murman Railway, in latitude about 68° N. The ascents were all carried out with one theodolite only, the balloon being given a vertical lift of, theoretically, 500 ft. per minute. The high latitude in which the observations were obtained renders them of value. There were at Murmansk 57 occasions on which the surface wind was in the north-east quadrant, and on 10 of these—that is, 17·5 per cent. of the total—the wind backed continuously up to 2000 feet. On the other hand, there were 164 occasions on which the surface wind was not in the north-east quadrant, and in only 5 of these—that is, 3·0 per cent. of the whole—did the wind back continuously upward. At Murmansk three ascents reached to a height of 40,000 feet, where two of the winds were N.W. and one S.W. Two ascents reached to 60,000 ft., where both winds were S.W. Seven ascents reached 20,000 ft., at that height four of the winds were S.W. and two N.W. Of the ascents carried out at Archangel only one reached 20,000 ft., where the wind was southerly. Of the ascents at Lumbushi, six attained a height of 20,000 ft., giving two north-westerly winds, three north-easterly, and one southerly.

The Climate of Khartoum.—Physical Department paper No. 9, prepared by Mr. L. J. Sutton, has recently been issued by the Ministry of Public Works, Egypt. The discussion deals with the meteorology of Khartoum, which place was installed as a second-order station in 1900, and is approximately 390 metres above sea-level. Maps of isobars are given for the several months which show the normal distribution of pressure over the surrounding region, which is of great help in following the changes of weather conditions which occur at Khartoum in the different seasons. It is during the period from the middle of June to September that the weather conditions are most disturbed. Thunder-storms and *haboobs*, or storms of wind, are frequent, and the short rainy season is experienced. In October to May there is

an entire absence of rain. The observations are discussed for the period of twenty-two years, from 1900 to 1921. Atmospheric pressure varies very regularly throughout the year; a minimum is reached about the beginning of May, and a second minimum occurs about the beginning of October. The diurnal range of the barometer is very regular and does not vary much in the course of the year. The coldest month is January, with a mean temperature of 22°·5 C.; the warmest month is June, with a mean temperature of 34°·1 C. The short rainy season causes a second minimum, 31°·2 C. in August. The second maximum temperature occurs about the end of September, approximately, the same time as the second minimum of pressure. Diurnal range of temperature is greatest, 14°·5 C., in April, and least, 10°·1 C., in September. Statistical values are also given of humidity, vapour pressure, cloud, sunshine, wind, and the upper winds. The amount of rainfall is small, averaging only 148 mm., or rather less than 6 in. for the year; nearly 90 per cent. of this falls in July, August, and September. The discussion will serve as a specimen for other stations.

Goldfields of Western Australia.—The Department of Mines of Western Australia has issued an important description of the gold deposits of Western Australia, written by Mr. A. Gibb Maitland. The author classifies the gold-bearing deposits under the following five heads: 1. Simple or fissure veins, carrying auriferous quartz with or without accessory minerals. 2. Composite veins or lodes, which are made up of a number of more or less parallel lenticular veins. 3. Sheeted zones, consisting of a series of closely spaced and parallel veins, generally of small dimensions. 4. Stockworks, which are irregular networks of small auriferous quartz veins. 5. Shear zones or bands of schistose rocks, impregnated with various sulphides, iron pyrites often predominating, and containing little or no quartz. In addition to the above classification, the author, when discussing the individual goldfields, also mentions the so-called "lode formations," which he defines as "impregnations of zones of previously existing rocks and confined largely to shear zones, characterised by much crushing and fracturing as well as the deposition of quartz along such fractures." It would appear that such lode formations are especially important in the Boulder and Kalgoorlie districts of the East Coolgardie gold-field, which is itself by far the most important of the Western Australian gold-fields, having produced over 17 million ounces of gold out of a total of 31 million ounces produced by Western Australia, whilst no other individual goldfield has produced above 3 million ounces. The gold production of Western Australia reached a maximum in the year 1903, when the output was just above 2 million ounces; since that time it has been gradually declining, until in 1918 it was only 876,511 ounces, but the account here published shows that there is good reason to hope that the present output may be reasonably expected to be maintained for a considerable time to come.

The Earth's Magnetic Field.—In the issue of *Terrestrial Magnetism and Atmospheric Electricity* for March-June, Dr. L. A. Bauer gives the chief results of a preliminary analysis of the earth's magnetic field for 1922 based on the British Admiralty magnetic charts for 1922 and those of the United States Hydrographic Office for 1920 corrected to 1922. He finds that the field at any instant is compounded of an internal field having a potential and representing about 94 per cent. of the total, an external field also having a potential and a non-potential field of about equal strengths. The time change of the field is equally complex. On the whole, during the past 80 years the north end of the axis of the internal field has moved slowly towards the west and south, and the intensity of magnetisation has decreased at the rate of 1/1500 of itself per annum. The intensity over land areas is greater than over ocean areas in the same latitude, and the decrease during the past 37 years greater over ocean parallels than over land parallels of latitude.

Production of Smokeless Fuel.—A pamphlet entitled "The Story of the Scott-Moncrieff Retort for producing Smokeless Fuel," printed by Moultons (Printers) Ltd., Brighton, contains material of some historical interest in connection with the efforts which have been and are being made to solve the problem of the low-temperature carbonisation of bituminous coal for the production of smokeless fuel. It deals with the recent and pioneering efforts (dating back to 1870) of Mr. W. D. Scott-Moncrieff. Since 1921 he has been engaged in experiments made at the Newhaven Gas Works in order to perfect a retort for which "final success" is claimed. In an enclosed analytical report are given tables of results of carbonisation trials which seem typical of those to be expected from the carbonisation of Durham and Yorkshire coals at temperatures about 600° C. The fuel produced is stated to be "smokeless and suitable for transit," and the "results exceed all expectations." Insufficient evidence is adduced to enable the reader to judge the validity of these claims. One can only await with interest the appearance of further details, with the hope that, if a solution has been found of a problem which has proved so baffling, both on the technical and the economic sides, credit will fall to one of the pioneering workers.

Oxidation of Carbon.—The well-known method of oxidation of organic substances by a mixture of chromic and sulphuric acids has been recently re-examined by J. L. Simon, and the results, some of which were unexpected, have been communicated in a series of notes to the *Comptes rendus* of the Paris Academy of Sciences. With the usual mixture of potassium bichromate and sulphuric acid some compounds are completely, others only partially, oxidised. The substitution of silver bichromate for potassium bichromate in the mixture was found to give complete combustion in some cases where the classical mixture gave only partial oxidation. Interesting and unexpected results were obtained on applying these two mixtures to the oxidation of the various forms of carbon. Pure graphite, using the silver oxidising mixture, was completely oxidised to carbon dioxide (with a trace of carbon monoxide) in half an hour at 100° C.: in the absence of silver the combustion was partial, from 66 per cent. to 72 per cent. being burnt. In a later communication (July 23) it is shown that the deficit in the absence of silver is related to the constitution of the compound, and the aromatic compounds can be clearly distinguished from others by the different figures given by the two reagents. As regards the different forms of carbon: in the presence of silver, graphite is completely burnt, diamond is not oxidised at all, while for various forms of charcoal, coke, and coal, only from 1 per cent. to 6 per cent. is burnt. The fact that it is possible to oxidise graphite by thirds is in agreement with the view of a hexagonal distribution of the carbon atoms, and there is a marked experimental difference between graphite and certain varieties of black carbon which it is natural to attribute to a difference in constitution.

Fossil Human Bones, possibly of Pleistocene Age, found in Egypt.

AT a meeting of the Royal Anthropological Institute, held on July 17, Prof. C. G. Seligman, president, in the chair, Dr. D. E. Derry described the fossilised human bones recently discovered in Egypt, which, on the ground of their condition, he is inclined to regard as of Pleistocene age. The discovery is one of very considerable importance, as this is the first occasion on which fossilised human bones have been obtained from Egypt. Early in January of the present year Mr. Guy Brunton, while excavating for the British School of Archæology in Upper Egypt, found at Gau-el-Kebir, on the east bank of the Nile, about thirty miles south of Assiut, a remarkable collection of bones, mostly animal, but with pieces of human bones mixed with them in the heap. Some of the bones, including the human fragments, were heavily mineralised, while others were only partially so, and some not at all. The whole collection was contained in an Early Dynastic grave, and had obviously been placed there for some purpose. Among the bones were carved bone and ivory objects of the XIXth Dynasty. The presence of the latter is explained on the assumption that this was the site of a workshop for the manufacture of articles in bone and ivory, and that the great heap dumped into the pit of an early grave represented the workman's material. The presence of freshwater oyster shells attached to some of the bones proves that they came from the river, or, what is more likely, from a swamp fed by the river, which in all probability was much nearer the site of the discovery than it is now. The bones exhibit evidence of having been exposed for a long time to the mineralising influence, as they are very heavy, black, and highly polished, probably from the friction of waterborne sand.

The first evidence of human fossil bones in the heap was found by Mr. Brunton. This consisted of the right half of a frontal bone. Afterwards the whole heap, probably about two tons of bones, was gone through and several other fragments both of skulls and limb bones were recovered. Pieces of three skulls were found, as well as part of a mandible. Fragments of hip bones, upper and lower limb bones, and an axis vertebra were also obtained. Two skulls are represented only by the frontal bone of each. These are remarkable for their small size and shallowness, with consequent small brain capacity. The third skull consists of the whole right parietal bone with a large part of the left parietal, welded into one piece. As it stands this appears to have been a well-shaped head with a maximum cranial breadth of 143 mm. This fragment is, however, much more heavily mineralised than the two frontal bones, which would appear to have belonged to a more primitive race. Some very unusual anatomical features are exhibited by the mandibular fragment and also by the piece of a right ilium.

The position in which the bones were found precludes the possibility of assigning them to any geological period; but an examination of the animal remains by Prof. Watson has revealed the presence of at least two extinct animals, a crocodile and a buffalo, both of Pleistocene date, while the mineralisation of the human fragments is as extensive as that of any of the animal remains.

In the discussion which followed the reading of the paper, Sir W. M. Flinders Petrie pointed out that in regard to the dating of the bones it must be remembered that owing to the constant and consistent deposit of mud by the Nile, amounting to about 3½ ft. in a thousand years, the bed of the river was rising continually. Any object deposited while the Nile was thus rising would be lost irretrievably beneath the mud. These bones must therefore have been deposited while the Nile was falling from six hundred feet above to one hundred feet below its present level. The date of deposition must therefore be at least 15,000 years ago, plus the time occupied by the fall of the river to the level of the swamp which had been postulated as the place of deposit.

Sir Arthur Keith said the discovery was extraordinarily interesting and puzzling. These fossilised bones, the first to be found in Egypt, presented no outstanding features marking them off from modern man, and no diagnosis of race was possible, but this did not preclude their high antiquity, and they might well be Pleistocene. Fragments of hippopotamus bone from the Nile mud, now at South Kensington, exhibited staining and a high polish exactly similar to that of some of Dr. Derry's specimens. Sir Arthur laid stress on the importance of the fringes of the great desert belt as the possible site of the evolution of our race; Dr. Derry's discovery, though we could not place it exactly, was of the first importance. Probably men of our type existed in Egypt more than 18,000 years ago, and populated Europe, possibly more than once. Prof. Seligman said the cubic capacity of 1040 c.c. of the small skull suggested a comparison with the smaller skulls from the Thebaid described by Dr. Randall-MacIver, and, in conjunction with the steatopygous predynastic figures discovered by Sir W. M. Flinders Petrie, pointed to the necessity of a further comparison with Bushmen skulls.

Recent Fisheries Investigations.

SOME very interesting reports, in continuation of Series II. (Sea Fishery Investigations), have recently been published by the Ministry of Agriculture and Fisheries. No 6 of vol. 4 is written by Mr. J. O. Borley, and describes the samples of bottom deposits collected in the southern North Sea by the vessels of the Marine Biological Association. The report is illustrated by charts and many very beautiful photographs. The deposits are graded in various ways, partly by mechanical sieving and partly by a method of levigation, and the results show a correspondence between the average sizes of the particles and the transporting power of the current systems. In general the particles are coarsest where the tidal streams are most rapid, and *vice versa*. It is not improbable that there is attrition of particles on the sea bottom, but this cannot be very great. At 20 fathoms (that is, not far from the average depth of the North Sea) the currents are competent to grade bottom materials: at this depth wave action on the surface has a notable effect at the bottom.

No. 1 of vol. 5 is a summary of very extensive market statistics, collected in regard to the cod, during the years 1913–14. No. 2 of vol. 5 is highly important. It is written by Mr. H. J. Buchanan-Wollaston, and deals with the spawning of the plaice in the southern North Sea (the Flemish Bight) during the years 1913–14. The method is an extension of the Hensen quantitative plankton one, but novel and beautifully manageable mathematical methods of dealing with the results have been developed: some of these are highly ingenious, and have, perhaps,

application to problems other than those for which they have been devised. The results are interesting almost to the degree of being "sensational." In January of 1913–14 the rate of production of plaice eggs over the whole area sampled was 180,000 millions per 3 days, and in February the rate dropped to 157,000 millions per 3 days. That works out at about two million million eggs per month and about five million million per year. To produce these eggs some twenty millions of female plaice at least must have been required. The rate of mortality is very high, and only about 10 to 30 per cent. of the eggs hatch out. The production was far higher in 1914 than in 1911.

No. 3 of vol. 5, written by Mr. J. O. Borley and his collaborators, deals with the plaice fisheries during the war years, and discusses the results of the special investigations made in various parts of the British sea-fishery area. The report and recommendations of the plaice committee of the International Fishery Council are appended.

No. 4 of vol. 5 breaks entirely new ground so far as the British sea fisheries are concerned. It is an account of the various kinds of gear now used in sea fishing in England and Wales, and has been written by Mr. F. M. Davis. The descriptions are clear; the drawings are very well done, and the Report represents a vast amount of very careful local investigation.

J. J.

The Floor of the Valley of Ten Thousand Smokes.

THE amazing display of fumarole action over an area of some fifty square miles, which arose in association with the volcanic outbreak of Mt. Katmai in Alaska in 1912, was described and illustrated by its discoverer, R. F. Griggs, in NATURE, vol. 101, p. 497 (1918). In 1920 (vol. 104, p. 595), J. W. Shipley, of Winnipeg, chemist to the first Katmai expedition, gave an illustrated account of the "great mud-flow" through which the vapours fume, and he attributed the material to an eruption of Mt. Novarupta, preceding that of Katmai. He concluded that the spreading of the volcanic dust and scoriæ down the valley towards the Bering Sea was assisted by rains, and that heat from below had hardened the surface and produced the cracks that traverse it.

The National Geographic Society, which organised the expedition led by Dr. Griggs, has now begun the publication of a series of scientific memoirs on special features of the district, following on the general description that was noticed in NATURE, vol. 111, p. 269 (1923). No. 1 of the "Katmai Series" of contributed papers is on "The Origin and Mode of Emplacement of the great Tuff Deposit of the Valley of Ten Thousand Smokes," by the well-known petrologist Clarence N. Fenner, of the Geophysical Laboratory of the Carnegie Institution of Washington.

The author finds, from a thorough study of the valley-floor, that the tuff was erupted from a large number of vents that opened along fissures mainly occurring in the lowland, and that these fissures determine the present lines of fumaroles. The fragmental material flowed while hot enough to char all vegetation in its path; no doubt it was still liberating gases, and the phenomena of Mount Pelée of Martinique were repeated. Katmai exploded somewhat later, since its ashes rest upon the volcanic detritus connected with the fumaroles.

Most of this detritus consists of highly siliceous glass, which has caught up basic matter from older igneous rocks; the mixed blocks possibly come from the moraines around Novarupta, the cone of which is formed of a soda-rhyolite that has penetrated and mingled with a dark medium andesite (p. 56 of memoir). But the author regards it as more likely that similar rock underlies the valley generally. Jurassic sandstones and shales have been blown to fragments by the explosions in the valley-floor; but the source of the andesitic admixture has not been traced here or at Novarupta.

Dr. Fenner's conclusion is that a sill of igneous rock penetrated the sedimentary series beneath the valley, burst into explosive activity along the cracks that opened, and deluged the country with fragmental matter that continued to give off gases and to spread as a quasi-liquid towards the coast. The numerous beautiful photographs accompanying his contribution, including several of Novarupta, complete its value as a petrological study carried out mainly in the field. We may now regard the Valley of Ten Thousand Smokes as one of the finest examples of the uprise and emanation of magmatic waters, and as a further reminder that igneous rocks as they reach us in hard specimens are something very different, both chemically and physically, from their representatives in the cauldrons of the crust.

GRENVILLE A. J. COLE.

Cultivation of Metal Crystals by Separation from the Gaseous State.

F. KOREF describes experiments on the deposition of crystalline tungsten on a wire consisting of a single tungsten crystal, which is heated electrically in a mixture of hydrogen and tungsten hexachloride vapour in an electric oven.[1] When the oven is fairly cool (about 110° C.) and the pressure is kept down to 12 mm. of mercury, the wire being raised to 1000° C., the metal deposits in crystalline form, growing from the unit crystal, so that the dividing line between the two is scarcely visible in a magnified section, which, when etched, shows the characteristic structure of a tungsten crystal. The external form shows more or less distinct crystalline surfaces and edges, though the surfaces are not perfectly plane, being sometimes concave cylindrical, while the edges are not always sharp. It is concluded, however, that the whole mass forms one crystal, which has grown from the original crystal wire. The number of bounding surfaces seems to depend on the direction of the crystal axis in the original wire, the prism being four-, six-, or eight-sided. The diameter can be increased from 0·05 to 0·15 mm., the temperature being kept constant during the deposition by regulating the heating current.

Although the original wire is flexible the crystal grown from it is brittle; but it becomes flexible after being heated for a few minutes to 2500° C.; no difference in the structure can be observed after this annealing, either microscopically or by X-ray examination. Burger has made a similar observation on tin crystals, obtained from molten tin. Apparently the atoms do not alter their positions during the heat treatment; but in some way, possibly by rotations about their centres, come into new relative relations to one another, and link together more perfectly to form a stronger and more flexible whole.

If the attempt is made to cultivate the crystal beyond the dimensions given above, the surfaces become deformed by the growth on them of numerous small pyramids, the molecules (atoms) no longer

[1] *Zeit. Electrochem.*, 28, pp. 511-517, December 1, 1922.

taking their places in regular fashion on the surfaces of the original crystal; but aggregating themselves about certain minute elementary crystals formed on the surface, which act as "buds" about which further growth takes place. When the pressure and temperature of the oven are high, this takes place from the commencement, and there is no regular crystal growth; but a deposit is formed in scaly layers round the original wire, which is either spongy or dendritic in character.

At the correct temperature and pressure the wire will continue to grow as a single crystal in spite of preliminary deformations, such as twisting, winding into a helix, or even drawing through a die. An attempt was made to draw down the annealed cultivated crystal into a fine wire, in the hope that further cultivation would be possible upon it; but this failed owing to the fact that the whole pressure coming on the edges overloaded the structure. The resulting wire no longer formed a single crystal; and when additional tungsten vapour was deposited on it, each of the small crystals of which it was composed grew independently; the resulting wire was brittle, and could not be made flexible by heating. A similar result was obtained with an ordinary tungsten wire, which did not consist of a single crystal; in this case it was found that heating to 2500° C. for fifteen minutes caused a great many of the small crystals formed at first to unite, so as to give a much coarser structure. This welding of small into larger crystals, without mechanical pressure, has not, apparently, been previously observed.

State Afforestation in 1921–22.[1]

THE Forestry Commissioners, who have just issued their third annual report, were appointed in November 1919, to carry out a definite programme of afforestation, involving the planting of 150,000 acres of new land in the ensuing ten years, the cost to be defrayed from the Forestry Fund, a sum of 3,500,000*l*. voted by Parliament for the whole period. Acquirement of land, planting operations, and other activities, including education and research, were proceeded with according to plan during the first two years; but the unfavourable financial position of the Government necessitated a reduced programme in the third year, so far as expenses were met with out of the Forestry Fund. Fortunately the Commissioners obtained a large grant out of the Unemployment Fund, and their operations have practically not been restricted. During the year ended September 30, 1922, the Commissioners expended 244,414*l*. out of the Forestry Fund, and 154,017*l*. out of the Unemployment Fund, in all 398,431*l*., a sum in excess of the normal programme.

The new land acquired for State afforestation during 1921–22 amounted to 23,937 acres. The Commissioners now possess 92,426 acres of plantable land. The area planted by the Commissioners in the year was 10,693 acres; and in addition to this, 10,192 acres were planted by private owners and corporations by means of grants, which were given on condition that unemployed labour should be used. These figures are very satisfactory. The usefulness of forestry for relief work is abundantly shown in the report, which is replete with statistics of the areas and species in the various plantations and nurseries.

Grants in aid of higher forestry education, in all 2206*l*., were given to the University schools at Oxford, Cambridge, Bangor, Armstrong College, and the two Agricultural Colleges at Aberdeen and Glasgow. The Commissioners have now three schools for training woodmen, at Parkend (Forest of Dean), Chopwell (Co. Durham), and Beauly (Inverness-shire), at an annual cost of 10,160*l*. On research and experiment, the expenditure was 6126*l*. Experimental plots of various species of trees are now 120 in number. Investigations are being carried out in regard to Chermes, *Phomopsis Douglasii*, tree growth on peat, larch hybridisation, etc.; and a census of woodlands is in progress.

[1] Third Annual Report of the Forestry Commissioners. Year ending September 30, 1922. (H.M. Stationery Office, 1923.) Price 1*s*. net.

The British Medical Association.

THE meeting of the British Medical Association at Portsmouth began on July 20, and the address of the president, Mr. C. P. Childe, was given on the evening of July 24 to a large audience, among whom were a number of distinguished visitors largely from the Oversea Dominions. The president in his address made a strong plea for better housing conditions in the industrial centres, and insisted that an enormous amount of the time and money which is at present being spent on the treatment of diseases like rickets and tuberculosis could be saved if adequate care were given to the housing problem, for in his opinion the absence of fresh air and sunlight in many of the crowded industrial centres was in itself largely responsible for the widespread occurrence of these diseases.

The detailed work in the sixteen different Sections went on from July 25 to July 27, during which a very wide field of subject was under discussion.

In the Section of Pathology and Bacteriology there were discussions upon diseases of the stomach and their methods of investigation, by Dr. C. Bolton; the value of serological tests in diagnosis, by Prof. H. R. Dean; and one on the part played by fungi in disease, by Dr. Castellani. Demonstrations were given, in the afternoons, of specimens which had been collected, forming a museum of very great interest.

In the Section of Radiology a discussion was opened by Dr. R. W. Salmond on the X-ray examination of the urinary tract. During the discussion it was evident that different weight was given by radiologists to the value of screen examinations of the region of the kidney.

The second subject for discussion in this Section was that of medical diathermy, opened by Dr. E. P. Cumberbatch, and followed by Dr. C. A. Robinson, who gave a detailed account of the treatment of gonorrhœa by means of diathermic currents; the temperature which can be tolerated by the tissues is sufficiently high to cause the death of the causative micro-organism, and beneficial results ensue.

In the Section of Tuberculosis a discussion was opened by Prof. Reyn, of Copenhagen, on the subject of the artificial light treatment of lupus and other forms of tuberculosis. From the clinical investigations which have been continued during a large number of years at Copenhagen, the conclusion has been reached that the results obtained in the treatment of lupus by means of ultra-violet light, initiated there by Finsen, are much improved if the local intensive treatment is supplemented by a general irradiation of the whole body. Dr. Sequeira reported a similar result from his experiences at the London Hospital; Prof. Russ thought that it was now possible to assign to certain parts of the spectrum their particular function in this form of therapy, and if this were the case selection of the best form

of radiation source became an important consideration.

The social aspects of tuberculosis were discussed in this Section as well as in that of Public Health.

A large exhibition was organised representing practically every aspect of medical work. This was supplemented by additional exhibits of interest to special Sections, such as radiology, pathology, parasitology, anatomy, etc., but considerations of space do not allow of more detailed notice here.

The meeting was very largely attended. The work of the local committees resulted in a very wide choice of excursion to the visitors, which was highly appreciated by them.

Einstein and the Philosophies of Kant and Mach.

THE Bulletin de la Société Française de Philosophie for July 1922, which has just been published (Armand Colin, Paris), contains the report of the reception of Prof. Einstein in Paris on April 6, 1922. It is of exceptional interest, for Einstein did not make an original communication, but assisted at a discussion of the theory of relativity.

Prof. Langevin introduced the discussion, and Messrs. Hadamard, Cartan, Painlevé, Perrin, Becquerel, Brunschvicg, Le Roy, Bergson, Meyerson, and Piéron took part. It elicited from Einstein two pronouncements of special significance in regard to the relation of his theory first to Kant and secondly to Mach. We quote them in full. The first was in reply to M. Brunschvicg, who had said that the Kantian philosophy in separating a *container*, space and time, from a *content*, matter and force, had ended in antinomies, while Einstein's conception, which is characterised by the fact that *container* and *content* are inseparable, had delivered us from them. To this Einstein replied: "I do not think my theory accords with the thought of Kant, that is, with what that thought appears to me to be. What appears to me the most important thing in Kant's philosophy is that it speaks of *a priori* concepts for the construction of science. Now there are two opposite points of view: Kant's apriorism, according to which certain concepts pre-exist in our consciousness, and Poincaré's conventionalism. Both agree on this point, that to construct science we need arbitrary concepts; but as to whether these concepts are given *a priori* or are arbitrary conventions, I am unable to say."

The second pronouncement was in reply to M. Meyerson, who had challenged him to declare how far he was in agreement with the theory of Mach. Einstein replied: "There does not appear to be a great relation from the logical point of view between the theory of relativity and Mach's theory. For Mach, there are two points to distinguish: on one hand there are the immediate data of experience, things we cannot touch; on the other there are concepts which we can modify. Mach's system studies the existing relations between data of experience; for Mach, science is the totality of these relations. That point of view is wrong, and, in fact, what Mach has done is to make a catalogue, not a system. To the extent that Mach was a good mechanician he was a deplorable philosopher. His view of science, that it deals with immediate data, led him to reject the existence of atoms. Probably were he still with us he would change his opinion. I would like to say, however, that on the other point, namely, that concepts can change, I am in complete agreement with Mach."

The Life-Cycle of the Protozoa.

PROF. C. A. KOFOID delivered, on December 27 last in Boston, an address as vice-president of Section F (Zoology) of the American Association for the Advancement of Science and as president of the American Society of Zoologists, on the life-cycle of the Protozoa (*Science*, vol. lvii. pp. 397-408, April 6, 1923). He remarked that the striking similarities of the most ancient fossil Protozoa to recent afford some ground for the inference that the Protozoa living to-day differ but little from those when life was young. A consideration of the accounts of the origin *de novo* of nuclei from chromidia leads to the conclusion that adequate evidence of such origin is lacking. Prof. Kofoid holds that, as sound cytological investigation of the Protozoa progresses, it becomes increasingly evident that the descent of the nuclei and the individuality of the chromosomes, found in the Metazoa, holds also for the Protozoa, and it may be inferred that the Protozoa are equipped with the essential structural basis—chromosomes and mitosis—for the mechanism of heredity.

The searcher for the origins of biological phenomena finds in the Protozoa a fertile but perplexing field. Here have arisen all the fundamental types of symmetry—spiral, leiotropic, dexiotropic, radial, bilateral, and modifications of these. Here also are several distinct types of mitosis, different locations of the centrosome, and extraordinary derivatives of this organ ranging from the nematocysts of Dinoflagellates to the complicated neuromotor system of the trichonymphid flagellates. Sex and sexual dimorphism have also had their origin in the Protozoa. Prof. Kofoid also refers to the universal occurrence of asexual reproduction in the Protozoa, and to the development after fertilisation of a multicellular stage, which he terms a somatella, in which there is generally no progress to the point of division of labour and differentiation of tissues, although the differentiation of sexual and somatic cells occurs in some cases, *e.g.* Volvox. The sequence of events within the cyst of Entamœba—involving elaboration of glycogen and the formation of the chromatoidal substance with its relation to the growth processes—is regarded as suggestive of the sequence in the egg and of the relationship of specific yolk substances to cleavage and differentiation in the metazoan egg. The observations of Jameson on maturation in the Sporozoa show that the haploid condition persists throughout the period of growth and asexual reproductions, while the diploid lasts but one cell-generation. Such conditions give occasion to wonder whether or not sexual reproduction may not have been elaborated gradually and independently within widely different groups in the Protista, and afterwards in them and in higher forms of life the diploid state has extended its domain more and more throughout the life-cycle.

Prof. Kofoid considers that the life-cycle of the malaria parasite—the zygote, the multicellular stage which follows and leads to the formation of sporozoites, which on introduction to man undergo growth and asexual reproduction to form merozoites, and the eventual production of gametocytes—may be compared with the fundamental processes of fertilisation, cleavage, asexual reproduction, and gametogenesis in the Metazoa, except that histogenesis and organ differentiation do not appear. He believes it may perhaps be helpful and serve to facilitate progress if we emphasise the similarities of organisms and seek to find the common processes underlying them all, rather than to emphasise their differences and thus obscure our vision of fundamental problems of life.

Science in Poland.[1]

IN 1881 the Mianowski Institution was founded at Warsaw with the object of promoting the interests of science in Poland. During many years the Institution had to struggle with the suspicious hostility of the Russian Government; notwithstanding bureaucratic cavil and quibble, the Institution edited between 1881 and 1916 more than 1000 volumes of scientific publications (originally written in Polish or translated), assisted hundreds of Polish scientific men in their work, subsidised various laboratories and research institutes, and accomplished much other valuable scientific and national work.

In 1918 and 1919, as soon as Poland was free, the influence and activity of the Institution expanded in a most satisfactory manner. In 1920 a meeting of 533 Polish men of science, coming from all parts of the country, was held at Warsaw, under the auspices of the Institution, with the object of considering, from various points of view, the needs and claims of science in Poland and the immediate prospects of intellectual development of the country. Volume 3 of "Nauka Polska" contains most of the addresses delivered at the Congress. It deals, of course, with many subjects treated by different writers in a variety of tone and of style; it is impossible, however, not to be struck with the glowing patriotic enthusiasm and the noble attachment to the cause of science shown in its pages.

In the inaugural address Prof. Jan Rozwadowski, professor of comparative linguistics in the Jagellonian University of Cracow, takes an uncommon and highly interesting view of "Science and Life." Prof. Rozwadowski would almost suggest that even science may countenance much that is superficial, futile, irrelevant, and sometimes even insincere. Of acute criticism scientific men are rarely tolerant; yet this address, even if it contains debatable matter, shows delightfully how little right they have to throw stones at indifferent or ignorant outsiders. The width of thought, the balance and wisdom shown in this lecture are very remarkable.

It is impossible in a short article to deal with the wide range of discussion contained in other essays; we must content ourselves with enumerating some further titles. "Independence of Science and Research," "Science and Education," "Science and Art," "Social Aspects of Science," "Science and the State," "Organisation of Scientific Research," "Polish Physiography," "Science and Economic Life," "Polish and International Science"—such are the subjects treated by various writers in an interesting or inspiring manner.

The fourth volume of "Nauka Polska" contains much that is valuable and interesting both in matter and scope. Reference may be made to a collection (pp. 81-286) of essays discussing the prospects and possibilities of scientific research in small towns or in the country, far away from libraries, laboratories, and the inspiring influence of university surroundings. Eighteen authors present us with a survey of scientific work that can be accomplished in remote parts of a large country such as Poland. Particularly valuable is Prof. Banachiewicz's contribution on "Amateur Astronomy," an article remarkable for the ability with which a variety of sound information has been epitomised, technical language, as far as possible, being avoided. In a very interesting essay Prof. Birkenmajer gives a list of gifts and benefactions to the Jagellonian University of Cracow in the fifteenth and sixteenth century, beginning with the gift by Queen Jadwiga of Poland, in 1399, of her jewels and other precious objects for the re-erection and endowment of the Jagellonian University, founded by her grandfather in 1364. This noble example was followed by many later benefactors. Another noteworthy feature of the volume is a short but very suggestive essay by Prof. Rozwadowski on "Science, Art, and Religious Belief." We notice also the following contributions: "National and International Science," by Prof. Gawroński; "Longevity of Chemists" (and particularly of Polish chemists), by Prof. J. Zawidzki; "Organisation of Science in France and the United States of N. America," by Messrs. Drzewiecki and Znaniecki.

In conclusion we can only say that we have laid down these volumes with a feeling of real sympathy and warm appreciation.

Formation of Organic Compounds from Inorganic by the Influence of Light.

DR. O. BAUDISCH contributes to *Science* of April 20 a very interesting account of work carried out by him on the photo-chemical production of organic nitrogen compounds and the influence of iron on nitrate reduction.

The purely chemical investigations originated from bacteriological experiments in which the author found that, in the case of cholera bacilli, the reduction of nitrates stands in direct relation to the oxygen respiration of the bacteria and also to their iron content. A somewhat analogous catalytic effect was discovered in investigating the reduction of nitrites by means of glucose in carbonate solution. Although no reaction takes place, even on heating under pressure, in the absence of iron, the smallest trace of an iron salt is sufficient to bring about the reduction of a large amount of nitrite. Under these conditions nitrates remain entirely unattacked, but are instantaneously reduced to nitrites even in the cold in the presence of oxygen and ferrous salts, an observation of considerable importance in connexion with biological reduction processes.

In contact with moist air, ferrous bicarbonate rapidly absorbs oxygen, yielding a labile peroxide compound, a reaction which the author compares to the fertilisation of an ovum. This is capable of forming a co-ordinated complex with the potassium nitrate, which then splits off an oxygen atom. Reduction of the nitrite is then assumed to proceed further to the extremely reactive potassium nitrosyl, K(NO), which at the same time reacts with organic substances present, especially aldehydes, to form carbon and nitrogen containing compounds. In this reaction ferrous bicarbonate and oxygen assume the rôle of light.

Ferrous bicarbonate peroxide is also capable of giving up the loosely linked oxygen molecule to oxidisable compounds, just as hæmoglobin absorbs oxygen and gives it back again for oxidation or dehydrogenation processes. The reaction is selective and depends upon the affinity of the compound to be oxidised, to form co-ordination compounds with the iron.

A comparison is drawn between the processes outlined above and the reducing action of soil bacteria, and it is concluded that the chemical reactions are, in both cases, very similar. The bacteria which do not need light most probably use the energy of the iron peroxide in rendering nitrates available for protein formation.

University and Educational Intelligence.

CAMBRIDGE.—Mr. T. Basil Buxton has been appointed as the first occupant of the newly created chair of animal pathology.

LEEDS.—The University has appointed Mr. J. A. S. Ritson to be professor of mining in the University, in succession to Prof. Granville Poole, who has been elected to a professorship at Armstrong College, Newcastle-on-Tyne. Mr. Ritson was educated at Uppingham and at Durham University (Armstrong College), where he graduated with distinction in mining and surveying, and has had considerable practical experience of colliery management in various parts of the country. He acted for some time as personal assistant to Sir William Walker, late Chief Inspector of Mines, and is at present senior inspector of mines in the Cardiff district.

ACCORDING to *Science*, the degree of doctor *honoris causa* of the University of Strasbourg has been conferred upon Dr. Simon Flexner, director of the Rockefeller Institute for Medical Research.

THE honorary degree of doctor of science of the University of Wisconsin has been conferred, according to *Science*, upon Prof. The. Svedberg, of the University of Uppsala, in recognition of his work on colloid chemistry and as director during the past term of the research work of the University.

A PROSPECTUS of the Faculty of Engineering of the University of Bristol, which is provided and maintained by the Society of Merchant Venturers in the Merchant Venturers' Technical College, Bristol, has just reached us. Courses of study are available at the College for persons intending to engage in civil, mechanical, electrical, or automobile engineering, and particulars of these courses are given in the prospectus. The ordinances and regulations relating to degrees and diplomas in engineering subjects are included, and some particulars of the Bristol Sandwich system of training engineers are also given. The prospectus can be obtained from the Registrar of the Merchant Venturers' Technical College, Bristol.

THE May issue of the *Phoenix*, the magazine of the Imperial College of Science and Technology, contains a brief account of two comparatively recent diploma courses inaugurated at the Royal School of Mines, dealing with the technology of oil and mining geology. The former course was started in 1913 in order to provide the petroleum industry with men thoroughly trained in certain branches, especially oil-geologists and chemists. The principles of drilling and allied oilfield-engineering are dealt with exhaustively, but the practical work is wisely left to the post-graduate stage of a student's training, when, engaged on work in an actual oilfield, he acquires that experience under far better conditions and in much shorter time than would be possible with an experimental rig designed for intermittent academic instruction, even if this were available. The application of geology to metalliferous mining is another advance made within recent years, and qualified mining geologists, as distinct from mining engineers, have not been long available in Great Britain. This state of affairs was remedied by the introduction of a mining geology course, which, like the older established course in mining, requires four years for its completion; arrangements are also made whereby an associate in either subject may, on working for a fifth year, acquire the double associateship in both mining and mining geology, the combined knowledge of these two subjects, and the wider training and qualification obtained, constituting attainments in every way essential to those whose ambition it is to rise high in their future profession. In both the technology of oil and mining geology courses, the importance of outdoor field-work is insisted on, and a great deal of the student's time is taken up with geological and topographical surveying.

STATISTICS of Public High Schools in the United States (Bulletin, 1922, No. 37) show that the school population has been doubling itself fairly regularly every ten years since 1890, the actual figures for that year and the end of each subsequent decade being: 202,963; 519,251; 915,061; 1,857,155. This rate of increase is about the same as that shown by statistics of secondary-school pupils in England and Wales during the past ten years; but whereas in the United States the pupils in the public high schools in 1920 were 1·76 per cent. of the total population, in England and Wales the percentage in secondary schools was only about half that figure. Of all secondary pupils, those in public high schools in 1920 formed 91 per cent. (in 1890, 1900, and 1910—68, 82, and 89 per cent. respectively), those in Roman Catholic high schools and academies 4 per cent., and those in other private institutions 5 per cent. The number of pupils to a teacher in the public high schools, after rising from 22·3 in 1890 to 25·5 in 1900, fell to 22 in 1910 and 20·5 in 1920. In private institutions the number fell from 13·2 in 1890 to 10·9 in 1900 and 10·5 in 1910, and rose to 12·3 in 1920. The tendency towards concentration of pupils in large schools is reflected in a sharp rise in the number of pupils per school from 89·6 to 139·5 in the public schools and from 65·9 to 88 in the private schools between 1910 and 1920.

THE rôle of the text-book in the public schools of America is subjected to some candid criticism in the annual report for 1922 of the president of the Carnegie Foundation for the Advancement of Teaching. Where text-books are prescribed by the State legislature the publishers' contracts run into millions of dollars, and editions vie in size with the season's "best-seller" novels. The criticisms are directed not so much at the dangers of collusion between publishers and legislators, which have been greatly diminished, as at the influence on school curricula of the large profits incidental to such large editions. To a teacher the production of a new text-book which shall obtain the approval of the State education department is the only road whereby his professional knowledge, experience, and talents may lead to affluence, and a vast amount of industry and ability has been devoted to this work. Many of the books produced are excellent, but their very excellence has accentuated two unfortunate tendencies: towards the multiplication of courses and of studies, and excessive separatism in teaching. "A reform of the school curriculum, planned to return once more to a conception of the school along simpler and more sincere lines, would find itself confronted with the fact that the means of instruction provided by the text-book publishers and the text-book writers and accepted by the authorities are . . . small doses administered at fixed times from stated text-books." This pigeon-holing system, under which the pupil's separate unrelated studies neither interest him nor give him a perspective, is of course not peculiar to the United States, nor are there wanting systematic attempts to displace it there. It is by way of revolt against it that the "project" method is now being encouraged in America, especially in elementary schools.

Societies and Academies.

SYDNEY.

Royal Society of New South Wales, June 6.—Mr. R. H. Cambage, president, in the chair.—A. L. **Kroeber**: Relationship of the Australian languages. Native terms for a number of fundamental concepts, chiefly names of body parts, were transcribed into a standardised orthography, and the data for each concept were entered on maps. Schmidts' fundamental separation of South and North Australian languages seems unnecessary. The languages are divided into groups, 8 southern and 7 northern; of 11 stems, each appears in a majority both of northern and southern groups, and each of 22 others in at least two southern and two northern groups. Genetic unity of all Australian languages seems probable.—J. **Read** and G. J. **Burrows**: Note on the dilution of ethylenebromohydrin with water. When ethylenebromohydrin is diluted with water a continuous absorption of heat occurs until a dilution of about 80 per cent.; further dilution from about 75 per cent. to 10 per cent. is attended by a continuous evolution of heat. Upon reversing the process an initial positive thermal effect is followed by a negative thermal effect. The volume of the solution is always less than the combined volumes of the two components: at 20° a maximum contraction of 1·07 per cent. occurs at a concentration of 50·041 per cent., corresponding closely with the ratio $1C_2H_5OBr : 7H_2O$. Density and viscosity measurements afford no indication of hydrate formation.—G. **Taylor**: The warped littoral around Sydney. Pt. I. The region within one hundred miles of Sydney is dominated by warps to the north, west, and south. Of these the well-known Blue Mountain monocline is the largest. The area is subdivided into 15 geographic regions symmetrically arranged about an east-west axis through Botany Bay. The central portion forms a "stillstand," bounded to the west by three silt-lakes along the Nepean. The coastal features are also symmetrically arranged. Port Hacking is a geographic parallel to Port Jackson, as Illawarra is to the Tuggerah coast. Sydney is unique in that a city of a million people is surrounded on almost all sides (at 50 miles distance) by a belt of country with scarcely an inhabitant. This is a result of geographic controls.—A. R. **Penfold** and R. **Grant**: The germicidal values of the principal commercial eucalyptus oils and their pure active constituents, with observations on the value of concentrated disinfectants. From commercial eucalyptus oils, and also the waste products obtained therefrom after rectification, cheap disinfectants having a high germicidal value can be manufactured. The crude oils gave coefficients varying from 5 to 12, while the pure constituents varied from 3·5 up to 22·5. The germicidal activities of the crude oils is due to certain aldehydes, alcohols, and phenols.—M. **Henry** and W. L. **Hindmarsh**: *Stypandra glauca* (a suspected poison plant). Experiments on thirty-two animals of five species, carried out in five different months and over a space of three years, were entirely negative. Sheep fed solely on *Stypandra glauca* for twenty-five days remained perfectly healthy.

CAPE TOWN.

Royal Society of South Africa, June 20.—Dr. A. Ogg, president, in the chair.—Sir Thomas **Muir**: Note on the successive differentiation of a product of linear functions.—J. Steph. v. d. **Lingen**: The differential bactericidal effect of the visible spectrum. The author discussed the results of Bie, Marshall Ward, Downing, and Russ, and also those obtained by Bayne-Jones and himself. In the work of these investigators the technique was to expose a culture for a given time and then to incubate it for 24 hours or more. On the results of the incubation conclusions were drawn with regard to the bactericidal effect of the various regions of the spectrum. The author described a new method for studying the bactericidal effect. Filters were placed in front of a series of small boxes (chalk boxes) each of which contained four nutrient agar slopes. After inoculating the slopes with bacteria they were placed in the boxes, which fitted into an incubator. In front of the incubator rows of tungsten lamps were placed so that the distribution of light was uniform on the cultures. By adjusting the intensity of the light to a suitable value, the inhibitory and bactericidal effects of the various regions of the spectrum could be studied, as well as the effects of total illumination and total darkness.—J. P. **Dalton**: On the attraction-coefficient for substances of low critical temperature. Some years ago the author found the dependence of van der Waal's a upon temperature for isopentane using Young's saturation data, but at the time sufficient saturation data were not available for testing the law of dependence for other substances. Since then the brilliant researches of Kamerlingh Onnes and his collaborators at Leyden have made available accurate saturation data for other substances of low critical temperature, and their results have been used to determine the constants of the above relation for argon, oxygen, nitrogen, and hydrogen. For these four substances a can well be represented as an exponential function of the temperature, and the agreement between the values of a calculated from the experimental data and those yielded by an equation of the type $\log a = \alpha - \beta T$ is very good.—C. W. **Mally**: X-rays as a means of detecting imperfections in fruit. An effort to find an infallible means of detecting internal defects in export fruit led to a trial with X-rays. Radiographs reveal the internal structure in detail. The ensemble of sound fruit is harmonious, whereas defects cause conflicting shadows to appear in the radiograph. The presence of fungal or bacterial organisms which produce decay is indicated in the radiographs by structural details being more or less obscure. This makes it possible in pathological research to determine with a great deal of certainty whether or not any given fruit that is to serve as a culture medium is sound and also to record the progress of the organisms by means of radiographs at regular intervals. The practical application to fruit inspection depends on satisfactory visibility on the fluoroscopic screen being attainable.

Supplement to NATURE

No. 2807 AUGUST 18, 1923

The Adaptational Machinery concerned in the Evolution of Man's Body.[1]

By Prof. Sir ARTHUR KEITH, F.R.S.

INTRODUCTORY.

TELEOLOGY, a word so familiar to readers of the works of Archdeacon Paley and of Sir Charles Bell, has disappeared from the vocabulary of scientific men. Darwin killed it; he put an end to natural theology and to Bridgewater treatises. Yet all those wonderful contrivances which Paley culled from the animal kingdom remain true; they are facts which have to be explained. The human hand is, as Bell maintained, a most effectively designed structure;[2] a modern evolutionist can still study with profit the account he gave of the mechanical contrivances to be seen in every part of the human body.[3] Modern discovery has served but to heighten our sense of wonder at the ingenuity which Nature has lavished on the human body. The means she has installed for fighting infection and internal disorders are almost beyond belief. In complexity and in efficiency of design the human brain far excels any invention or organisation the most fertile imagination of man has yet conceived. Engineers, in designing all their contrivances, ensure stability during emergencies by allowing a "factor of safety"; in all systems of the human body the "factor of safety" is more than ample. In this respect the human body has been made almost "fool-proof."

If, then, teleology has disappeared from our evolutionary vocabulary, its substance remains; we have still to find a rational explanation for the manifest contrivances of the human body; a "doctrine of adaptation to purpose" is still a necessity. The followers of Paley had an easy task; they had but to wave a theological wand, and the origin of all of Nature's contrivances was instantly explained. But we followers of Charles Darwin have a much more laborious undertaking in front of us; we have to discover and demonstrate in the body of man, in the developing embryo, and in the growing child the actual machinery which has wrought its marvellous and purposive organisation. In this lecture, given in memory of Huxley at his old hospital and school, I propose to see how far modern discovery has revealed the nature of the adaptational machinery of man's body.

[3] Illustrations of Paley's "Natural Theology." An Appendix to Lord Brougham's edition.

HUXLEY AS HUMAN ANATOMIST.

Of all the men who stood round Darwin as helpful critics, Huxley has come out best; time has upheld his judgments and shown that when he doubted he had the intuition of genius. His opinions concerning the evolution and adaptations of the human body are of particular value, for, at two periods of his career, he was a close student of human anatomy. The first of these was spent in this school, from 1842 to 1846, when he passed from his seventeenth to his twenty-first year, and qualified for the practice of medicine. Then, after sailing the high seas of zoology for a dozen of years, he again made the human body one of his main themes of interest, and it remained so for a period of fully twelve years—from 1858 to 1871—when he again returned to the larger problems of zoology and evolution. No doubt his return to the study of man's body in 1858 was to correct certain doctrines which Owen was promulgating concerning it, and to support Darwin's "Origin of Species," which was issued at the close of 1859.

HUXLEY ON TELEOLOGY.

How, then, did Huxley explain the origin of those excellent contrivances in the human body which had commanded the admiration of so many generations of anatomists? It was not until 1876, when he was in the fifty-first year of his age and at the zenith of his intellectual power, that he gives us a glimpse within his mind and permits us to see how he viewed teleology—the science of adaptation. In the early spring of 1876 he gave a lecture in Glasgow, selecting "the hand" as his subject—the text which had served Sir Charles Bell for a Bridgewater treatise. How had man come by his hand? By what evolutionary means had the clumsy climbing anthropoid hand become the dexterous grasping hand of man? If Huxley had believed, as Lamarck, Spencer, and Darwin did, that "functionally wrought" modifications could become hereditary—that a simian stock, were it to use its arms and hands as man now uses his, would in the course of

many generations come to have human hands and arms—then the evolution of the human hand was a comparatively easy problem. At no time of his life did Huxley believe that the effects of use or disuse did become hereditary. In 1890 he wrote:[4] "I absolutely disbelieve in use-inheritance as the evidence now stands."

Having thus rejected the only known means by which useful or purposive modifications of the body can be brought about, we turn with some degree of curiosity to his lecture in Glasgow[5] on the evolution of the hand. The exact title which he gave to his discourse was "On the Teleology and Morphology of the Hand." This is how he approached the problem of adaptation:

"To be a teleologist and yet accept evolution, it is only necessary *to suppose that the original plan was sketched out—that the purpose was foreshadowed in the molecular arrangements out of which the animals have come.*" Then twelve years later (in a letter to Romanes in 1888) he wrote[6]: "It is quite conceivable that every species tends to produce varieties of a limited number and kind, and that the effect of natural selection is to favour the development of some of these, while it opposes the development of others, *along their predetermined line of modification.*"

Huxley as an Evolutionary Predestinarian.

Thus it will be seen that Huxley, on the evidence then at his disposal, had come to the startling conclusion that the shaping or controlling forces which, in due season, were to give man his hand, lay latent in the germ-plasm of that simian stock which ultimately blossomed into human and anthropoid shapes. The evidence which forced Huxley to take up the position of an evolutionary predestinarian must have been indeed cogent. Only a few years previously (1868), Sir Richard Owen had given utterance to a somewhat similar belief, when he wrote:[7] "Generations do not vary accidentally in any and every direction, but in preordained definite and correlated courses." Huxley, as was afterwards the case with Weissmann, believed that the creative machinery of evolution lay in the womb of the germ-plasm.

Modern Predeterminists.

Manifestly, if the evolutionary fate of man is already determined by the properties of his germ-plasm, as Huxley believed, it is a truth of the utmost consequence to medical men. We cannot, if this be true, in any way control the future of humanity, except by the application of Darwin's law of selection. Man's destiny lies hid in the potentialities of his germ-plasm. Huxley's belief is widely shared by modern students of evolution. No one has had better opportunities of noting how evolution has worked in shaping higher mammals during the Tertiary period than Dr. H. Fairfield Osborn, of the American Museum of Natural History. He finds ample evidence of a "definite or determinate origin of certain new characters, which appear to be *partly* a matter of hereditary disposition."[8] He finds that evolutionary tendencies, like that which leads to the formation of horns and antlers, may lie latent in an ancestral stock, and only become manifest at subsequent times and in different ways in certain of the descendants of that stock. That evolutionary manifestations of this kind have taken place in the evolutionary history of the higher primates—the group to which man belongs—there can be no doubt.

In recent times this conception of evolution working out its effects in predetermined directions has been forcibly suggested by Bateson. In his presidential address to the British Association in Australia in 1914 he expressed himself thus:

"If then we have to dispense, as seems likely, with any addition from without, we must begin seriously to consider whether the course of evolution can at all reasonably be represented as an unpacking of an original complex which contained within itself the whole range of diversity which living things present. . . . At first sight it may seem rank absurdity to suppose that the primordial form or forms of protoplasm could have contained complexity enough to produce the diverse types of life."

In this passage Bateson plainly suggests that the machinery of evolution has proceeded on its way, untrammelled by any outward circumstance, right from the first appearance of living protoplasm. We have here the doctrine of evolutionary predestination stated in its most extreme form. Whether such a belief as this of Bateson is well founded or not, it shows us that one who has given a lifetime to the study of variation and of heredity is of opinion that the evolutionary machinery which has given man his brain, his hand, his foot, and his posture has worked out its effects undisturbed by the surrounding conditions of life. In brief, functionally wrought modifications have had no part in shaping the human body.[9]

Before proceeding to set out the evidence concerning the nature of the machinery which shapes man's body, there is another opinion, akin to that of Huxley, which

[4] Life and Letters, by his son, Leonard Huxley, 1900, vol. 2, p. 268.

[5] Life and Letters, vol. 1, p. 456. I have been unable to obtain any published account of this lecture save that given by Mr. Leonard Huxley in the "Life and Letters."

[6] Life and Letters, vol. 2, p. 188.

[7] Anatomy of Vertebrates, vol. 3, p. 808.

[8] The Origin and Evolution of Life, 1918, p. 278. In this work the reader will find references to literature bearing on predeterminism in evolution.

[9] It is unnecessary to give here a list of the men who have concluded that plants and animals tend to vary in definite directions, whatever be the circumstances in which they are placed. The evidence relating to this matter has been very ably summarised in recent times by E. S. Russell, Form and Function, London, 1916; and by Prof. R. Anthony, "Le Determinisme et l'Adaptation Morphologique," *Archives de Morphologie*, Paris, 1922.

deserves to be considered here. It was given by Prof. G. Elliot Smith,[10] and is founded on a prolonged and intimate study of the brain of man and of the brains of animals which have a close structural relationship to man:

"And if all the factors in his (man's) emergence are not yet known, there is one unquestionable, tangible factor that we can seize hold of and examine—the steady and uniform development of the brain along a well-defined course throughout the Primates right up to man, which must give us the fundamental reason for man's emergence and ascent. . . . Thus at the dawn of the Tertiary period there were developed the germs of all the psychical greatness which, in the million or so of years that have followed, culminated in the human mind."

Without a doubt the brain of the great anthropoids is but an elaborated edition of that which serves the needs of monkeys, and, in turn, the brain of man, while framed on exactly the same plan as that of the great anthropoid, far transcends it in complexity of elaboration. In the evolution of these three stages, represented by the brains of man, anthropoid, and monkey, we are witnessing, not an unpacking, but an ever-increasing degree of specialisation as von Baer and Spencer recognised long ago. In the organisation of the brain of the monkey we see something which is comparable to the civilisation of a primitive people, such as the aborigines of Australia; in that of the anthropoids, one which may be compared with the life led by a semi-civilised people, such as the natives of the Congo, while in the human brain we reach a stage of complexity represented by the highest modern civilisation. Whether we speak of brains or of civilisation, the machinery of evolution must be of an analogous nature in both of them. What is the nature of this machinery?

How Adaptations appear during the Development of the Embryo.

Since the time of Darwin and of Huxley our knowledge of the factors which take a part in controlling the development, and therefore the evolution, of the brain and of its appended sense organs, such as the eye, the ear, and the nose, has entered a new phase. We shall take the formation of the eye as our first example because in design and execution it far excels any camera yet invented; it has been the theme of many a teleological sermon, and a consideration of its development will take us right to the heart of our subject—the origin of purposive or adapted structures. After the publication of the "Origin of Species," Mr. J. J. Murphy, of Belfast, cited the eye as a structure which could not be accounted for by any theory of selection then propounded. "It is probably no exaggeration to suppose," wrote Mr. Murphy,

that in order to improve such an organ as the eye at all, it must be improved in ten different ways at once, and the improbability of any complex organ being produced and brought to perfection in any such way is an improbability of the same kind and degree as that of producing a poem or a mathematical demonstration by throwing letters at random on a table.[11]

Darwin, with that customary candour which regulated his search for truth, quotes in full this cogent and, to my way of thinking, just criticism, and Darwin's reply was that the eyes of men, as of animals, did show slight degrees of individual variation, and that he could conceive the twilight eye of the owl or of the lemur as having arisen by a selection and accumulation of these minute variations. Mr. Murphy modestly estimated the parts of the eye which must undergo a simultaneous modification, if sight was to remain efficient, as ten in number; he would have been inside the mark if he had said ten thousand. We cannot conceive how the countless elements which go to the construction of an eye can assume their appropriate place, form, and function unless we postulate a machinery which regulates the development and growth of every one of them.

The existence of such a machinery was made evident by experiments on tadpoles carried out by Dr. Warren H. Lewis at Baltimore from 1903 onwards.[12] The optic cup, which ultimately forms the retina of the eye, grows out from the wall of the brain towards the embryonic skin or ectoderm. When this cup comes into contact with the ectoderm, the overlying cells begin to proliferate and arrange themselves so as to form a transparent or crystalline lens. Dr. Lewis transplanted the outgrowing optic cups of tadpoles, and found, if they were placed under the ectoderm of the neck or of the belly, that the result was the same; an optic cup caused the overlying cutaneous cells to alter their nature and form a lens. Dr. Lewis realised the significance of his discovery; in the developing embryo, although only of certain species, one group of living cells can enslave and control the behaviour of another group. He gave us a glimpse of the kind of evolutionary machinery employed in fashioning a highly purposive structure such as the eye. Any one who has followed the success with which physicists have unravelled the structure of the atom in recent years will not despair of an equal success attending the efforts of embryologists to uncover the means by which one

[10] British Association Reports, 1912 (Dundee), pp. 575-598.

[11] The Variation of Animals and Plants under Domestication, 1868, vol. 2, p. 222.

[12] "Experiments on the Origin and Differentiation of the Optic Vesicle of Amphibia," *Amer. Jour of Anat.*, 1904, vol. 3, pp. 507, 805; 1907, vol. 7, pp. 144, 259. See also Spemann, *Zoolog. Jahrbuch*, 1912, vol. 32, p. 1.

group of embryonic cells regulates the growth of a neighbouring group.

Our knowledge of the machinery by which the growth of embryonic tissues is controlled and shaped is likely to increase rapidly, for in recent years embryologists have copied the methods invented for the study of bacteria, and have succeeded in growing the live tissues of embryos in artificial media. It has been proved time after time that the epithelial cells of an embryo, such as the living cells of renal tubules, if grown apart from other cells, spread outwards in a more or less disorderly manner; but if connective-tissue cells are added to the culture, then the epithelial cells form orderly ranks, just as they do in the kidney tubules of the embryo.[13] Carrel[14] found that the juices of embryonic tissues contain substances which cause cultures of living cells of any kind to proliferate rapidly and to continue alive for an endless series of generations. Thus it will be seen that the machinery which regulates the behaviour of groups of cells within the body of the embryo is one of the utmost complexity, and yet is of a kind which can be handled and studied by biologists. Nor can we doubt for a moment that the machinery of development and of growth which we find at work in the embryo is also the machinery of adaptation and of evolution. In every phase of the development and evolution of the human hand we see this adaptational machinery at work.

Behaviour of Young Nerve Cells.

There is no need to tell even the uninitiated that the brain and nervous system of man comprises many thousands of millions of microscopic units or nerve cells. Each unit of the brain has its appropriate place in a tremendously complex system, and has its special duty in dealing with the tide of messages which flood that system in every hour of conscious and subconscious life. When a child is born all the nerve centres which regulate the complex apparatus of breathing start into instant and effective operation. When the mother's teat is placed within its lips the nerve centres which regulate this intricate series of actions start to work as if they had served an apprenticeship before they appeared in the orderly development of the babe's nervous system. We cannot yet explain satisfactorily the means by which such really marvellous evolutionary results have been reached, such as reflex nerve centres, ready for action at the moment of birth, but at least we can claim to have before us a prospect of giving a rational account of how the various groups of nerve units are assembled so as to give a functional result.

Our present knowledge of this matter is largely due to the researches of Dr. Ariens Kappers[15] of Amsterdam, and to investigations made by his pupils. Nerve cells may not remain in the sites at which they are developed; in their younger stages they have the power to migrate. Dr. Kappers found that a group of embryonic nerve cells or neuroblasts, which are afterwards to control definite sets of muscles and therefore to be concerned in carrying out certain actions of the body, migrate towards the sources of their information. Those young executive nerve cells take up their permanent stations at points most suitable for the performance of their life's work. If we conceive a mob of war-seasoned men to deploy automatically and to take up effective battle-stations we have before us a picture of what is to be seen taking place among the nerve cells in the brain of the growing human embryo. Developing nerve cells send out processes which effect unerring contacts with other distant cell-groups of the body. Dr. Davidson Black[16] found that certain cell-groups on the cortex of the brain proceeded in their development only if the processes of another distant group of cells had entered into contact with them. We have here another instance of one embryological group of cells determining or controlling the development of another group. Enough has been said to show that the machinery which regulates the development and growth of the brain is one of the utmost complexity. We have no reason to suppose that it is of a kind which lies beyond the comprehension of the human mind, although it may take centuries of neurological inquiry to lay bare its nature. The one point we are certain of is that the factors which regulate the development, growth, and arrangement of the countless units of our nervous system do work in such a way as to produce an effective functional result.

The Evolution of Muscular Adaptations.

In no system of the human body do we find more instructive examples of mechanical adaptation than in the muscles which carry out the movements of our bodies and of our limbs. The nature of the machinery involved in the elaboration of muscular adaptations may be illustrated by the development of muscles which guard the mouth, eye, nose, and ear, and are concerned in expression. The bud which gives rise to the muscles on one half of the face begins at one localised site of the human embryo, a site in the embryonic neck, marked by the hyoid arch. From this site the young muscle cells or myoblasts migrate outwards, over the neck and scalp, round the ear, eye, nose, and mouth; as they reach their destinations they fall into ranks and take up such positions as permit

them, when fully differentiated, to perform effectively their respective functions. The influences which control their movements and regulate their dispositions we do not know as yet. But whatever the nature of these regulating forces may prove to be, we can see that they are exactly of the same kind as those which control the differentiation of facial musculature in monkeys and anthropoids. The degree of differentiation of the facial musculature of man is but the final stage of a continuous series of evolutionary forms to be traced in the faces of monkeys and anthropoids. The elaboration of the facial musculature runs more or less parallel to the elaboration of the brain.

The manner in which muscular adaptations arise may be better exemplified if we take a muscle which is concerned in purely mechanical actions, such as the latissimus dorsi. This muscle is concerned in pulling the upper arm backwards as in rowing. It works in the human body from a wide firm base, placed in the lower part of the back—one which extends from the sixth dorsal spine to the crest of the ilium. As points of origin it also utilises the lowest three or four ribs, and occasionally also the lower angle of the scapula. This muscle, occupying the lower half of the back, makes its appearance in the human embryo in the lower part of the neck, just below the embryonic shoulder-blade. By the end of the sixth week of development the army of cells which compose the muscle have extended or migrated downwards as far as the fourth rib, reaching the twelfth rib about the seventh week, and the iliac crest by the time the human embryo is two months old.[17] The success with which the developing muscle cells reach their ultimate destinations is one of surprising accuracy; they may take hold of a spine or a rib too far up or too low down, but the total result is always one which makes the whole muscle into an effective mechanical engine. Such variations may make the muscle a little less or a little more useful to the individual. The young muscle cells, when they have reached their definitive sites, arrange themselves in serried ranks, each rank hitched directly or indirectly to the lever through which the collective army of cells exerts its strength.

Now, this muscle has almost the same attachments in the gorilla and chimpanzee as in man; there is a greater range of individual variation in its points of origin; the marksmanship made by the migrating myoblasts is less accurate than in man. In the orang this muscle obtains no direct origin from the ribs, while in the gibbon five or six ribs are seized. In the gibbon, however, there is no direct muscular origin from the crest of the ilium. In the old-world monkeys, and also in their American cousins, the origin of the latissimus is restricted to the lower three or four dorsal spines; the origin from the iliac crest is slight or indirect; while the fibres rising on the side of the thorax are not directly attached to the ribs. Very occasionally one sees fibres rising from the lower angle of the scapula of monkeys, a variation in attachment which has become very common in man. In these variations of attachment we are seeing evolution at work, and its machinery lies in the forces which regulate or control the migratory movements of the young muscle cells.

Influence of Nerve-connections.

It is true that nerve fibres have entered, and formed a union with, the muscle mass in the neck before migration has set in; the nerves are carried along by the migrating muscle horde; differentiation of the muscle fibres begins at the point at which the nerve enters the muscle mass. When muscular fibres are fully differentiated they depend on their union with nerve fibres for a continuance of their health and life. But the migratory impulse, be that impulse what it may, lies not in the nerve union but in the muscle elements themselves, for Ross G. Harrison[18] found, if the limb of a developing tadpole were deprived of its nerve supply, the muscles still became duly differentiated in their usual stations.

Adaptations may appear first as occasional Variations.

Let us take another example to illustrate the manner in which a new muscular feature has been evolved in man's body. The muscles of the calf of man's leg have taken on an enormous growth to raise the heel in walking. The structure of the deeper muscle of man's calf, the soleus, has taken on an extremely complex and efficient arrangement of fibres; its origin from the posterior aspect of the bones of the leg is particularly extensive. In all dog-like or pronograde apes this muscle has a narrow origin from the smaller bone of the leg, the fibula, and this is also usually the case in the orthograde apes, or anthropoids. In man the origin of the muscle has undergone an extension, a large part migrating from the fibula and obtaining an extensive attachment to the tibia. But this extension to the tibia which is constant in man occurs as a frequent variation in all the anthropoids. Out of 8 gorillas examined, 3 had a tibial origin for this muscle; this was also the case in 2 out of 12 chimpanzees, 1 out of 8 orangs, and 2 out of 12 gibbons. In the anthropoids there is a tendency for the soleus to extend its origin to the tibia; in man this tendency

[17] Warren H. Lewis, Keibel and Mall's Manual of Human Embryology, 1910, vol. i. pp. 454-522.

[18] *Anat. Record*, 1908, vol. 2, p. 145; *American Journ. of Anat.*, 1906, vol. 5, p. 121; *Journ. of Experim. Zool.*, 1907, vol. 4, p. 239.

has become a fixed habit. This is but one instance of what is often to be observed in the study of human evolution, where an occasional variation in apes has become the established form in man.

How has this tendency to vary in a definite direction arisen? It is a direction which increases the functional efficiency of the human leg. Has this tendency arisen in apes as a result of the manner in which they climb? Or is it, as Huxley would have us infer, a tendency which is inherent in the developing soleus and has come into existence under the influence of some unknown factor which regulates the developmental movement of muscle cells? I think that Huxley's interpretation is the true one.

Let us take another example. Under the skin of the sole of man's foot lies a muscle known as the short flexor of the toes. In man all its four bellies, designed for the outer four toes, have a solid basis of origin on the bone of the heel; from such an origin the collective muscle can play a helpful part in maintaining the arch of man's foot. Now in the monkey's foot, while the muscle for the second toe arises from the heel, the muscles for the three outer toes retain a primitive origin from an adjacent surface provided by moving tendons. In the gibbon it is usual for the muscle of the third as well as of the second toe to have moved its origin to the heel; in the great anthropoids, particularly in the orang, the muscle of the fourth toe has also left the tendon and migrated to the heel; in man all four have moved. Here we see a human character arising as the culmination of a tendency which can be observed, to a greater or less degree, in the feet of all those animals which are most closely related to man, yet more primitive than him in structure. The migration of origin, on the part of the embryonic muscular cells, is of a useful or purposive kind. We cannot avoid the conclusion that the growth and development of young muscle cells are controlled by influences or means which work towards a functional result.

The Origin of a Muscle peculiar to Man.

Man possesses a muscle which is peculiar to himself—the peroneus tertius—and it will help us to understand how new structural features have been, or are being, evolved if we note the manner in which this muscle makes its appearance during the development of the leg and foot of the human embryo. The peroneus tertius raises the outer border of the foot and assists in applying the sole of the foot to the inequalities of the ground in walking. If we examine a hundred human legs we shall find ninety in which the peroneus tertius is a complete and separate muscle, but in the remaining ten we shall find some in which it is separated only to a greater or less degree from an adjacent and older muscle, the long extensors of the toes, and some in which it is quite unseparated from this muscle, as is the case in the legs and feet of anthropoid apes. In the gorilla one notices occasionally a tendency for the outer fibres of the tendon going to the fifth or small toe to stray or migrate towards the outer border of the foot. When we turn to the developing leg to ascertain how this new muscle makes its appearance in the human embryo, we find, towards the end of the second month of development, that the mass or colony of muscle cells which are to extend the toes, becomes separated from the common extensor mass of the leg, and that, in turn, the muscle cells which are to form the peroneus tertius separate or are cleft from the outer side of the long extensors of the toes—from the part concerned in extending the little toe and incidentally in turning upwards the outer border of the foot. The peroneus tertius represents a colony of muscle cells which have broken away from the parent muscle—the long extensor of the fifth toe. The tendon fibres have broken away from those going to the toe and migrated backwards along the outer border of the foot, thus giving them an advantageous position for the performance of their function in walking.

We have here all the properties manifested by developing muscle masses—a power of cleavage or separation, and a power of migration. What causes these outer muscle cells which are destined to act on the most external of the digits to break from the parent mass and assume a separate functional identity? I agree with Huxley that there are no grounds for believing that the behaviour of embryonic muscle cells is in any way influenced by experiences gained by adult muscle fibres. When vertebrate limbs came first into existence the muscle colonies which deployed to form the extensors of the toes, grouped themselves so as to get a functional result. In the case of the outer toe there was a double function, the extension of the toe and the everting of the foot. In the human foot the muscle cells which evert the foot have separated themselves from those which extend the little toe. The evolutionary machinery lies in the behaviour of the embryonic muscle cells or myoblasts.

Instances of Parallel Inheritance.

Let me cite two other examples which go to show that myoblasts possess evolutionary tendencies which work towards a purposive or functional end. The interosseus muscles of the hand and foot of monkeys arise, not from the adjacent surfaces of metacarpal and metatarsal bones, as they do in man, but from the bases of these bones, in the palm of the hand and sole of the foot. In the human embryo the interosseus muscles appear in the same palmar position as that which is retained in monkeys. In the most primitive of anthropoid apes—the gibbon, and also in the highest of South American monkeys—the howler monkeys—Ateles—the origin of the interosseus muscles have migrated so as to take a partial hold of the adjacent surfaces of the metacarpal and metatarsal bones. In the great anthropoid apes—the gorilla, chimpanzee, orang—and in man, these muscles have sunk in between and seized the adjacent surfaces of the metacarpal bones of the hand and metatarsal bones of the foot. This migratory tendency has seized upon, or become manifested in, the muscles of the hand as well as in those of the foot, although these members are subject to different functional influences. We can account for such evolutionary manifestations only by supposing that in a remote common ancestor of all the members of the higher primates there was a latent tendency in the myoblasts of the interosseus muscles to deploy

and group themselves in a new way, one which gave a better functional result.

Another striking fact is that the muscles which have become reduced or vestigial in man have also become reduced and vestigial, although usually to a less extent, in the anthropoid apes. All of these muscles, plantaris, palmaris longus, psoas parvus, latissimo-condyloideus, omo-cervicalis, etc., are laid down in a normal way during the development of the embryo; after being laid down retrogression sets in. We have here again to deal with functional tendencies. The machinery of reduction is resident in the processes which govern the development of structural systems in the embryo. As W. Roux supposed, there may be a struggle for survival between the system of cells which make up the body of an embryo.

The Adaptational Properties of Bone Cells.

By the fourth month of fœtal life young nerve cells and young muscle cells have taken up their definitive position and arrangement. On the other hand, white blood corpuscles retain all through the life of the individual the migratory power which is lost by most other cells of the body early in fœtal life. The cells which line blood and lymph vessels and those which line the peritoneal and pleural cavities [19] retain all through life a power to proliferate and produce new tissues which are of a purposive kind. Such cells retain the chief characteristic of embryonic cells—the power to arrange themselves as part of a functional complex. Bone cells also retain powers of purposive action. Nothing is better known than that, if a bone of a rickety child bends under the weight of the body, the bone cells lying in its concavity will proliferate and build a buttress to strengthen the shaft. It is not necessary for us to speculate here as to the exact stimuli which cause bone cells to behave in this manner; it is enough for our present purpose to note that they react to fulfil an end necessary for the occasion.[20]

John Hunter discovered the remarkable power which bone cells possess to remodel bones during growth. While bone cells are building at one part of a bone, they are, at another part of the same bone, busily engaged in taking down their previous handiwork. The co-ordinated manœuvres of the armies of bone cells concerned in the growth of the jaws and eruption of the teeth are extraordinary. When teeth are erupting and also long after they are cut, their bony sockets are being constantly altered and remodelled by the hundreds of thousands of osteoblasts embedded in the bone surrounding the dental roots. While new bone is being laid down on the outer side of the jaw under the gum, the corresponding bone on the inner side of the gum is being absorbed. But in the tooth socket itself the opposite is happening; new bone is being laid down on the inner side of the tooth socket, while it is being removed from the wall forming the outer side of the socket. New bone is being laid down under the roots so that the socket as a whole is being raised and moved in an outward direction. The crowd of osteoblasts involved in this operation are clearly co-ordinated in their action; they move on towards a functional result. Although we do not know the exact means by which their action is co-ordinated we have, in the qualities and tendencies, possessed by bone cells, part of the machinery of evolution. Cartilage cells, during embryonic life, must be co-ordinated in their growth and arrangement. In the fœtal hand we find they have fashioned the joints to meet the needs of the muscles which act on them, thus permitting harmonious movements of the wrist and digits. The development and behaviour of embryonic cartilage cells constitute part of the machinery of human evolution.

Co-ordination in the Growth of Bone, Muscle, and Nerve Cells.

I have dealt with the behaviour of young cells of bone, muscle, and nerve centres in the developing embryo in order that we may appreciate the complexity of the process involved in producing a new structural adaptation of the human body. When we sit up or walk, our vertebræ are balanced one upon another by means of a complex series of muscles acting upon an equally complex series of levers, the whole controlled by intricate groups of nerve cells situated in the spinal cord and brain. The anatomical evidence [21] leaves us in no doubt that the spinal mechanism of man has been evolved from one very similar to that now seen in the anthropoid apes. Indeed in the young chimpanzee and gorilla many of man's spinal adaptations are already present. In the evolution of a human from an anthropoid spine we have to conceive, (1) that the multitudes of bone cells involved in the building of vertebral processes of the embryo were so influenced in their operations that the levers they built were altered in strength, inclination, and form; (2) the countless myriads of myoblasts involved in the formation of the spinal musculature were so influenced that they took up new positions and effected new combinations; (3) the cartilage cells, which mould the contours of the intervertebral joints, were moved to alter the shapes of the articular surfaces so as to provide the needed contours; (4) the nerve cells of the spinal cord and brain, presiding over the reflex and voluntary movements of the spinal muscles, had to undergo increase in numbers, rearrangements in grouping, and readjustment of contacts. We have to postulate that in the human embryo there exists a machinery which co-ordinates the development and growth of all the diverse hordes of embryonic cells concerned in the formation of man's spinal mechanism and causes them to move in a direction which, at all stages of evolution, yields a harmonious functional result.

Theory of Hormones.

There is only one theory which affords a rational explanation of how such complex adaptations can be brought about—the theory of Hormones postulated by Starling in 1905.[22] Although Prof. Starling devoted

[19] An account of the actions and reactions of vascular tissues will be found in the writings of W. Roux from 1878 onwards. I have dealt with the adaptative reactions of peritoneal cells in Human Embryology and Morphology, 1921, 4th edition.

[20] I have dealt with the growth reactions of bone cells at some length (Menders of the Maimed, 1919, chapters xiv., xv., xvi., xvii., and xviii.)

[21] "Man's Posture: Its Evolution and Disorders," *Brit. Med. Journ.*, 1923, 1, pp. 451, 493, 545, 587, 642, 669.

[22] Prof. E. H. Starling, "The Chemical Correlation of the Functions of the Body." The Croonian Lectures at the Royal College of Physicians. *Lancet*, 1905, vol. 2, p. 339.

the greater part of his Croonian lectures to demonstrate the part played by chemical substances or hormones in co-ordinating the functions of the body he clearly realised that hormone control formed the basal machinery of all evolutionary processes in the animal kingdom.

"In the lowest organisms, such as the bacteria and protozoa, the only adaptations into which we can gain any clear insight are those to the environment of the organism, and in these cases the mechanism is almost entirely a chemical one. . . . In the lowest metazoa, such as the sponges, there is still no trace of any nervous system. The co-ordination between the different cells of the colony is still determined by purely chemical means. . . . If, as I am inclined to believe, all the organs of the body are regulated in their growth and activity by chemical mechanisms, similar to those I have described, an extended knowledge of hormones gives complete control of the body."

We are justified, on all grounds, in looking upon the human embryo, in the earlier stages of its developing, as a colony of protoplasmic units or cells, organised under a system of government controlled by hormones. Each member of the colony, we must suppose, has the power of circularising, by means of the hormone postal system, some or all of the other members of the colony in such a way as to notify its needs and compel their co-operation. With each step in the differentiation of the embryonic tissues there must be a further elaboration in the hormone system of intercommunication and government, until the fœtal stages are reached, when the growth-regulating substances become installed in special controlling centres represented by the glands of internal secretion—the pituitary, adrenal, thyroid, etc. We know that juices expressed from embryonic tissue contain substances which stimulate the proliferation and growth of living tissues; we know from observations already cited that one group of embryonic cells can control the manner in which another group develops, but we have to admit, also, that our knowledge of the action of hormones in fashioning the growth of organs is still in its infancy. The vista presented by this unexplored field of knowledge is infinite in extent and complexity, and will provide embryologists with many centuries of labour. Their labour will reveal in full the true nature of the machinery which underlies the production of structural adaptations which occur in every part of the animal body in every stage of its evolution.

The Significance of Acromegaly.

A long and close study of the bodies of men and women who have been the subjects of that strange disorder of growth known as acromegaly, has convinced me that the system of hormones, which controls and co-ordinates the growth of various organs and parts of the body is organised, like the nervous system, on a reflex basis. There are reflexes of growth just as there are reflex actions of muscles; both kinds of reflexes serve definite purposes in the economy of the body. The glands of internal secretion provide substances which control the action of organs and of parts of the body; they also produce substances which co-ordinate the growth of the organs or parts concerned in these actions. In the subjects of acromegaly the pituitary gland is enlarged and its structure more or less disorganised; the parts of the body which respond to hard toil, such as the hands, feet, and jaws, become greatly and irregularly overgrown. All the systems of the body—muscular, bony, respiratory, circulatory, alimentary, and renal systems—are involved; all show an abnormal degree and kind of overgrowth.

We find a clue to most of the growth disorders of the human body, such as acromegaly, in a knowledge of the mechanism of normal growth. Growth disorders—dwarfism and giantism—are but derangements of the various parts of the normal machinery of growth. Sir James Mackenzie regards the symptoms of illness, manifested by suffering men and women, as derangements of the normal reflex functions of their bodies. In a like manner we may consider disorders of growth, such as acromegaly, as a derangement of a normal mechanism—that which co-ordinates the response made by the various parts of the body to exercise and training. When a man passes into training, whether it be to use his hands as a labourer, his biceps as a blacksmith, his legs as a runner, or his arms as a rower—the responsive growth is not confined to the muscles of his hand, arm, or leg. All the bones of the body respond to a greater or less degree, so do the heart and lungs, so do all the systems of his body; he has to eat and digest more. We cannot imagine such a co-ordinated functional result being brought about, one which affects every system of the body, unless we postulate a controlling system of hormones. Nor can there be a doubt that acromegaly, in all its stages and degrees, represents a diseased manifestation of this adaptational system.

To fit all the bits of this puzzle into a connected whole we have to suppose that muscles in sustained action do emit certain substances which pass into the circulation and thus reach the pituitary gland. We have to suppose that in the pituitary these substances elicit responses leading to the emission of other substances which pass into the circulation and thus reach and influence organs which are correlated in action with the muscles directly involved. We have here all the elements of a reflex system—the pituitary serving as a chief centre or hormone-brain. In acromegaly the disordered condition of the pituitary leads to a flooding of the body with adaptative hormones after the most trivial of muscular actions, and hence its unregulated growth.

Barwell's Disorder.

In the Museum of Charing Cross Hospital, Huxley's old school, there is the skull of a boy which shows a very instructive disorder of growth. It is not a unique specimen; many cases of an exactly similar kind are known. The boy came into the hospital for treatment of a tumour-like swelling of the face, for which Mr. Barwell tied the right carotid artery. The boy died, and it was found that, on the right side of his skull, all those structures which are concerned in mastication, and only the structures concerned in this function, were greatly and uniformly hypertrophied. The condition was clearly produced long before birth, for all the teeth, including those of the milk dentition, were nearly twice the normal size on the right side of the mouth. So were the jaws and all the bony struts of the face which

support the jaws; so were the muscles of mastication, the temporo-mandibular joint—in short, all dental, bony, muscular, vascular, and nervous structures concerned in mastication. We cannot conceive how such disorders of growth could be so sharply limited to a single functional system unless we agree that the machinery which regulates growth and development is organised not on an anatomical, but on a functional basis.

Use-inheritance.

In the foregoing paragraphs an attempt has been made to picture the means by which the development and growth of the various cell groups, which make up the body of the embryo, are co-ordinated and controlled. Such evidence as we have justifies us in the belief that there is an automatic system of control worked by means of hormones, and that this machinery, in all its variations, tends to produce a functional or adaptational result. The very important question remains to be considered: can this machinery, which controls the differentiation of the tissues of an embryo, be influenced from without? Or does it, as Bateson believes, work on towards its destined result, in spite of all surrounding conditions and influences? The genital glands and their contents, of both man and woman, are exposed to all the substances, be they nutritive or hormonic in nature, which flood their circulatory systems. In 1906 J. J. Cunningham [23] applied the theory of hormones to the problems of heredity. He conceived it possible that the genital cells could be influenced, and so altered in their constitution, by hormones thrown off by all the organs and parts of the parent body. There is no inherent physical obstacle to prevent one from entertaining such a belief. Such a conception implies the possibility of hormones—function-regulating substances—of a parent coming into contact with and influencing the controlling action of the embryonic hormone-system. If it were possible, as is assumed in every form of Lamarckian belief, for parent products to come in contact with, and thus alter, the machinery which controls the growth of the embryo, it would be a consequence of the utmost import for mankind. By a full use of our brains, of our teeth, or of our hands, we might hope to influence the development and growth of the corresponding parts in our children.

Evidence of the Teeth.

I have selected the teeth to test the question as to the part played by use in the evolution of structural adaptations. There can be no doubt that the manner in which the crowns of man's sixteen upper teeth fit against corresponding surfaces of the lower sixteen, give us as fine a structural adaptation as we may hope to cite. There is the additional advantage that, as the teeth are the most persistent of fossil remains, we know more of this system in the forerunners of man and of living anthropoid apes than of any other parts of their anatomy. Further, in highly civilised races teeth are not only more liable to decay and to irregularities of eruption than in primitive races, but there is also, in civilised peoples, a marked tendency to a reduction in size and number of the dental series. We see, too, in the evolution of the dentitions of the higher primates, when the pattern of the enamel changes in one tooth, it changes in all of them; if one tooth alters, the opposing teeth have to alter in conformity; we see that if the dentition strengthens, all the members of the series participate; when reduction sets in, all the teeth suffer a reduction in a definite order. But these changes cannot be due to use, for the crowns of the teeth are laid down, and the opposing chewing surfaces fully formed, while the dental germs lie buried in the gums and long before the crowns come into use. When they do come into use, the teeth formed in the upper jaw possess the exact surfaces needed to oppose those of the lower jaw. After usage, especially in apes and primitive man, the opposing surfaces become worn off; if use had any effect here it would be to produce teeth with eroded crowns.

It is clear that functional adaptation, so far as concerns the production of teeth, is a property resident in the embryonic tissues; the effects of usage in the parent can have no influence on the machinery which shapes the dental crowns in the mouth of the fœtus and infant. If this is true of one system of the human body, it is probably true of all other adaptational systems—such as the brain, hand, and foot. Nature would have been foolhardy to entrust the future of any race whatsoever to the voluntary efforts or natural inclinations of the parents. As far as possible she seems to have safeguarded the progeny by isolating the gonads from the functional influences of the parental body.

The Germ-plasm can be permanently injured.

Yet there is one line of evidence which shows that the spermatozoa of the male and the ova of the female can be acted on or injured from without. Darwin [24] has related the case of a cow in which one eye was injured when she was in calf. The calf was born with the corresponding eye small and blind. In more recent years Marey [25] has recorded an identical result in a mare; one eye was injured when she was pregnant, and the foal was born with the corresponding eye small and blind. Hitherto we have been inclined to regard such cases as mere coincidences, but the well-known experiments of Guyer and Smith [26] provide a rational explanation. They injected into the veins of doe rabbits, about the end of the second week of pregnancy, doses of a substance which has a selective and toxic action on the lens of the eye. Many of the young were born with defects of the eyes—cataract of the lens being particularly frequent. When these young rabbits grew up and bred, many of their young showed the same defects. The developmental disorder could be transmitted in the spermatozoa as well as in the ova. These experiments show that the germ-plasm can be reached from without, and by means of a toxic substance can be permanently injured, so that progeny issuing from it will show ever afterwards a characteristic and localised defect. Stockard[27] induced permanent changes in the germ-plasm of guinea-pigs by exposing one generation of animals to extreme and continuous doses of alcohol. Dr. J. G. Adami[28] cites several instances of a similar nature, and has summed up the evidence relating to "the inheritance of acquired conditions in the higher mammals." Many of the cases recorded to prove acquired inheritance relate to changes which have been produced in the skin, particularly in its pigment-carrying cells. On the evidence which has accumulated there is good reason for believing that light can act upon epidermal and other elements of the skin in such a way as to effect changes in certain factors or elements of the germ-plasm. The observations and experiments made by J. T. Cunningham[29] on the colouring of flat fish, and the more recent observations which Dr. Kammerer[30] has made on salamanders exposed to light, and to dark backgrounds, can be interpreted only if we admit that reactions in the skin can affect the reproductive cells lying within the genital glands of the animals subjected to experiment. Notwithstanding this admission I do not think, as I shall mention later, that the loss of pigment in fair Europeans is due to any direct action of light on the skin. It is one thing to injure or influence the germ-plasm in such a way as to alter the machinery which controls the development of the embryo; it is quite another thing to alter that machinery in such a way as to make it produce a new mechanical adaptation. We know of no means by which the machinery of mechanical adaptation can be altered from without.

Are the Modern Conditions of Life altering the Germ-plasm of the Human Stock.

The admission that the genital cells can be injured or altered by substances circulating in the body of the parent is of the utmost consequence for mankind. The conditions of modern civilisation are making us the subjects of a colossal experiment. Six thousand years ago, our ancestors, scraping a subsistence from moor and shore, passed their days amidst the same conditions as surrounded the earliest types of evolving man. Man's body was adapted for rough fare and unregulated exposure. Modern civilisation has revolutionised the conditions of life in every detail. We use our brains, our skins, our muscles, our lungs, our teeth, stomach, and bowels, our hands and feet, for purposes which are new to them. Our tissues are kept soaked with juices containing substances which are still strange to them. Our crowded communities favour the prevalence and spread of all forms of infectious disorders in young and old. We are discovering that a rough and raw dietary contains certain elements which are essential for health. It would be strange if the evolutionary machinery of the human body kept on working in the same way as when the conditions of life were, if not simpler, yet much more primitive. A prolonged and minute comparison of human remains found in ancient and modern graves in England has convinced me that structural changes of a minor kind are affecting certain parts of the skeleton in at least one-third of modern instances. The narrow bony opening to the nose, with its jib-like nasal spine, its raised and sharp sill, so often seen in modern English skulls, are conditions never present in Englishmen of the pre-Roman periods. Contracted palates, crowded and defective teeth, deformed jaws, sunken cheek-bones do not become common in English graves until we reach the eighteenth century. The appearance of these structural changes in Englishmen cannot be attributed to the introduction of any new racial element from abroad. No doubt these facial changes are due in part to the soft nature of our food, and the disuse of our muscles of mastication.

Lack of use alone will not, however, explain the form taken by these structural alterations; they are injurious rather than helpful; they cannot be classified among the contrived adaptations. We have reason to suspect that defects of eyesight grow more common. There are grounds for believing that the great bowel, including the cæcum and appendix, becomes more liable to disorder and to disease with each succeeding generation. Twenty years ago Metchnikoff[31] expressed the belief that the great bowel of man had become a useless structure, and that he would be better off without it. The result of recent surgical experience has been to convince medical men that the man with a normal great bowel is an infinitely fitter and happier person than the man without one. The only question that remains to be settled is whether it is better to be with or without a colon which has become incurably diseased.

There is thus a certain amount of evidence to support the belief that certain parts of the body are less robust, some of them actually undergoing a structural change, in a considerable proportion of people living under modern conditions of life. There is also no doubt that these changes and susceptibilities occur much more frequently in some families than in others. To what extent these new features have become hereditary and therefore due to an injury of the germ-plasm, we cannot yet say. But in the light of experiments like those of Guyer and Smith, and of Stockard, medical men have grounds for suspecting that the source from which new generations of our race issue may not be invulnerable, that our germ-plasm may become tainted under the conditions to which our bodies are now subjected.

The Law of Recapitulation is only partially true.

In the foregoing paragraphs I have turned aside from my main thesis—the nature of the evolutionary machinery which has given man his gifts of brain and body. The nature of this machinery will never be understood by those who still harbour the belief that the human embryo, in its developmental stages, recapitulates the evolutionary history of the human body. I do not think any one familiar with the stages passed through by the developing human embryo would now agree with Huxley when he wrote: [32]—

[27] "An Experimental Study of Racial Degeneration in Animals treated with Alcohol," *Archiv Int. Med.*, 1912, vol. 10, p. 369; Proc. Soc. Experim. Biol. and Med., N.Y., 1911–12, p. 71; 1913–14, p. 136.

[31] The Nature of Man, translated by Dr. P. Chalmers Mitchell, 1904; see also Keith, "The Functional Nature of the Cæcum and Appendix," *Brit. Med. Journ.*, 1913, vol. 2, p. 1599.
[32] Collected Essays, vol. 2, p. 5.

" A man in his development runs for a little while parallel with, though never passing through, the form of the meanest worm, then travels for a space beside the fish, then journeys along with the bird and the reptile for his fellow-travellers ; and only at last, after a brief companionship with the highest of the four-footed and four-handed world, rises into the dignity of pure manhood."

It is true that we cannot explain the infinity of stages passed through by a human embryo, from the fertilised ovum, representing the lowest unicellular stage of living things, to the fully formed child, unless we believe that man, like all animals, has been evolved from the simplest of beginnings. But every one of these transitional stages represents a new form of being, never one of which has been seen at any stage of the world's history leading an independent adult existence. Every organ and part of the human body passes through an extensive series of developmental changes which receive a full and adequate explanation from the theory of evolution, but not one of these changes, from the first to the last, copies a form seen in any adult animal ; at every point of development old or recapitulatory phases are masked by the unceasing introduction of new and individual features. The student of the human embryo and fœtus is impressed not by its recapitulatory behaviour but by the manner in which new features are being intercalated. Such facts favour Huxley's view that the machinery of evolution works in the body of the embryo uninfluenced by adult experience.

The Use made by Nature of the Capitalistic System.

Scientific men do not need to be told that capital is needed for the development and improvement of an invention ; capital is as necessary for the progress of a civilisation as for the extension of a business undertaking. Nature discovered very early in the history of the world that capital is needed for evolutionary progress. A breakfast egg represents the capital set aside for the development of a fowl, and during the incubation period the stock of yolk makes possible any form of experiments which the embryonic cells may tend to make. In the higher mammals the capitalistic system has become fluid and elastic—represented by the mother's blood and milk. The placenta and all accessory structures needed for the lodgment of the young in the mother's womb were invented and elaborated by embryonic cells during the incubating stages in the development of lower vertebrates. The simple yolk capitalistic system, evolved and elaborated by the embryonic cells of lower vertebrates, became, in the higher vertebrates, transformed into the elaborate organisation which gives rise to the placenta, thus securing for the young months of free lodging. When we inquire into the nature of the process which gives rise to the placenta we find that it concerns certain embryonic cells which, in the lower vertebrates, proceed to form part of the belly-wall, part of the bowel, and part of the bladder. These same groups of cells in higher mammals have taken on themselves an entirely new purpose. Instead of proceeding to form the parts of the body just mentioned, they give rise to the placenta and membranes which envelop the embryo. Here we see that embryonic cells and the machinery which regulates their evolutions have inherent in them a power of working out the most intricate inventions and of effecting structural adaptations of the most serviceable kind.

The Genesis of Man's special Structural Features.

We need not be surprised, seeing how plastic and resourceful the embryonic tissues are, to find most—but not all—of man's characteristic features appear in a modified form as transitional phases in the fœtal stages of man's nearest allies—the anthropoid apes. Man's outstanding structural peculiarities have been produced during the embryonic and fœtal stages of his evolutionary history ; the corresponding and somewhat similar characters which appear in fœtal anthropoids become masked in these animals by the superaddition of coarser animal features which develop as their intra-uterine life closes, and particularly as their adolescent and adult stages are passed. At birth the brain of the baby gorilla is almost as big as that of the human baby ; but whereas the period of rapid growth continues in the human brain throughout infancy, the brain of the gorilla proceeds after birth at a slow pace. The human brain retains the rapid rate of fœtal growth for two years after birth. My friend Prof. L. Bolk[33] of Amsterdam, who has done so much to prove that man's distinctive characters represent a heritage accumulated in the fœtal phase of his development, has shown that the downward bend of the front part of the base of the skull, and the consequent backward position of the face, occur at an early point of development in all mammals. The cranial bend becomes undone and the face thrust forwards as development proceeds in all mammals, save in man, in whom these fœtal features are retained until, and throughout, adult life. The nearest approach to the adult human form occurs in the fœtal stages of anthropoid apes. The fœtal cranial bend is not a primitive or ancient character ; it was worked out in fœtal life ; never, until the evolution of man took place, did this feature survive to reach an adult stage.

Let us take another feature—man's hairless skin, and in the case of the white races its comparative lack of pigment.[34] In the chimpanzee fœtus, at the seventh month of development, the hair is distributed on the body exactly as in a baby at birth ; there is the same long and fine hair on the scalp ; the same smooth skin covered with a short, almost invisible down. The skin, too, which afterwards becomes deeply pigmented and black in the adult chimpanzee, at this stage is gray, tinged with a trace of brown. At a still younger stage the skin is almost free from pigment. The young of many of the higher primates are born with fair hair—often tinged with red. Fair hair is a fœtal character of primates which has become permanent in Northern Europeans and is found distributed

Akad. van Wetensch. te Amsterdam*, 1922, vol. 25, Nos. 7, 8 ; "On the Significance of Supraorbital Ridges in the Primates," *ibid.*, 1922, vol. 25, Nos. 1, 2 ; "On the Character of Morphologcal Modifications in consequence of Affections of the Endocrine Organs," *ibid.*, 1921, vol. 23, No. 9.

[34] See my Herter Lectures, "The Evolution of Human Races in the light of the Hormone Theory," *Johns Hopkins Hospital Bulletin*, 1922, vol. 33, pp. 155, 195 ; also Prof. C. S. Stockard's "Human Types and Growth Reactions," *Amer. Journ. Anat.*, 1923, vol. 31, p. 261.

sporadically in North Africa and Central Asia. Here again we see characters which were worked out in fœtal months passing on to become characters of adult life.

Such examples could be multiplied to a wearisome extent. I do not wish to minimise the number and importance of transient simian features which appear in the body of the human fœtus and infant; they are well known and of great significance. But I do desire to give a true interpretation to such human features as are represented by man's small face and jaws; his forehead, tending to be devoid of supra-orbital ridges; his large head poised on a long and relatively slender neck: they are features first produced in the fœtal stages of higher primates and now retained by man in his adult state. The tendency to preserve such fœtal characters is seen in certain genera of South American monkeys. But all the fossil progenitors of ape and man we have yet discovered have a face, jaws, skull, and neck of the more primitive and bestial type.

The Bearing of Fœtal Inheritance on Huxley's Conception.

I return to Huxley's disbelief in "use-inheritance" and to his conviction that animals—including man—tend to evolve "along their predetermined line of modification." It is clear that the mammalian placenta, particularly that kind of placentation which occurs in the womb of man and of anthropoids—identical systems—cannot in any way be accounted for by "use-inheritance." They have been worked out by properties inherent in embryonic tissues. The fact that the most characteristic features of the human body appear first in embryonic or fœtal life, and that human-like characters appear transiently in fœtal stages of anthropoid apes, the further fact that many constant structural modifications of man's body are seen as occasional variations of the ape's body, all bear out Huxley's dictum that evolution tends to evolve along predetermined lines of modification. The machinery of evolution works out its untrammelled ends in the embryo and the fœtus, except in so far as that machinery can be injured or deflected by what may be termed poisons of the germ-plasm. It is clear, too, that if we are to cast man's horoscope we can read the omens only in the tendencies manifested in his embryonic and fœtal stages. We can alter man's future only in that limited way discovered by Darwin—by applying his principle of selection.

A Simile.

To make my meaning clear, let me borrow a simile from human affairs. Some thirty years ago, in the incipient stages which led to the modern development of the great motor-car industry, small workshops sprang up in almost every town and supplied a car of local design for local needs. The struggle for survival set in, and successful types, ousting local types, led to the formation of great firms which catered for the needs of continents. The workmen engaged and the types of car made became specialised and standardised. These great firms, we know, keep an eye on the market—benefit by experience—and modify their types to suit demand. Invention succeeds invention in their workshops. But in the factory where human types of body and mind are produced I am presuming there is no intelligence department. I am also presuming, as Huxley did, that the workmen—the cells of the embryo—employed in turning out new human machines, are specialised into vocational, hereditary castes—each caste turning out its work in a certain way—a way which ensures a functional result. I am presuming, too, that the workmen represented by the embryonic cells are co-ordinated in their toil by an elaborate system of intercommunication—already described—the system of hormones. All hands in the human factory are co-ordinated—not by orders from managers or foremen, but by a self-regulating system of hormone-control which works out functional ends automatically. Variations—useful adaptations—are produced by a bias which is inherent in the machinery of control. The mere fact that I have to resort to so crude a simile shows how ignorant we still are of the machinery of animal evolution.

Conclusion.

John Hunter gave utterance to an important truth when he said man's bony and vascular tissues retained the same automatic purposive behaviour as is manifested by the lowest forms of organised life, such as the hydra. In the formative period of the human embryo, and on the phase when adaptational contrivances are being worked out in its heart, brain, muscles, and skeleton, the embryonic cells retain many of the purposive, almost conscious, attributes possessed by primitive unicellular organisms. No doubt the behaviour of embryonic cells, as of the simplest protozoa, will prove to be reflex in nature—mere protoplasmic reactions to appropriate stimuli. In bringing about the collective reactions of embryonic tissues, which mould them to form structural adaptations, we may presume that hormones play a leading rôle. The hormone system, to give the results it does, must be framed upon a teleological basis.

If we would rightly understand the evolution of the machinery of adaptation, or, what is the same thing, the machinery of government, in the developing body of an animal, we shall do well, as Herbert Spencer suggested, to study the evolution of a people rising from savagedom to civilisation. In the earlier stages of the evolution of human society we see that the machinery of government is represented by the automatic working of a herd-instinct—an instinct tending in all its operations towards the preservation of the community. The instinct is biassed in the direction of producing functional or effective results. We have to study what, in our present ignorance, we must call the "herd-instincts" of the vast community of protoplasmic units embraced by the body of a human embryo, if we would understand how the structural contrivances of the human body have been evolved. I, for one, believe with Huxley that the government which rules within the body of the embryo proceeds along its way altogether uninfluenced by occurrences or experiences which affect the body or brain of the parent. In short, man has come by his great gifts—his brain, his upright posture, his strange foot and his nimble hand—not by any effort of his own, but, like a favoured child of the present day, has fallen heir to a fortune for which he has never laboured.

Lord Grey's Bill for the Protection of Wild Birds.

WE have now for many years had legislation in Great Britain for the protection of wild birds, in addition to the much older laws relating only to game. The desirability for such protection has received increasing recognition on humanitarian and æsthetic grounds, and it is also to be hoped that there is a growing realisation of the importance of the subject from an economic point of view. The different Acts which have successively been placed on the Statute Book have had varying merit as judged by the wisdom of their intentions, but where they have all so lamentably failed is in their ineffectiveness. This grave fault has been remedied in the wise measure which Viscount Grey of Fallodon has introduced into the House of Lords, and, although his Bill has many other good points, it is probably on that ground that we should chiefly welcome it. The Bill was read a third time on July 30, and a copy of it, as amended in committee, is before us. It is greatly to be hoped that the House of Commons will similarly pass the measure next session.

The Bill aims at the repeal of all existing enactments on the subject, and at making complete provision on the new lines recommended in 1919 by the Departmental Committee on the Protection of Wild Birds. All birds to which the Bill applies—that is to say, all wild birds other than grouse, ptarmigan, partridges, pheasants, and black game—are divided into three categories, each of which is to receive its appropriate degree of protection, as follows:

> Category I.—Birds in this group, and their nests and eggs, are to be protected absolutely at all times and places.
>
> Category II.—Birds in this group, and their nests and eggs, are to be protected absolutely during the close season from the 1st March to the 31st July. (The Woodcock is to be protected from the 1st February to the 31st August, and the owners or occupiers of land may take the eggs of the Lapwing thereon up to the 15th April.)
>
> Category III.—Birds in this group, but not their nests and eggs, are to be protected during the close season from the 1st March to the 31st July except against the owners or occupiers of the land concerned and their accredited agents.

The birds included in the first and second categories respectively are listed in the schedules to the Bill, and the third category includes all the other birds. Roughly speaking, the birds in the first category are either species which are relatively rare or species of great usefulness, such as the owls, which it is desirable to encourage. Those in the second category are species which have not been considered quite worthy of the first but require special protection during the breeding

season. The Home Secretary or the Secretary for Scotland, as the case may be, is to be given power to transfer birds from one category to another or to change the dates of the close season. He may do this by general order or, with the consent of the local authorities, by local order affecting only a particular district; and with the consent of the owner and occupier of the land he may make a special order in support of an endeavour to create a bird sanctuary, even to the extent of giving all birds in the sanctuary the full protection of Category I. In exercising these functions the Secretary of State is to be assisted by an advisory committee.

The Bill also contains a number of special provisions, some of which are new and others of which are retained from existing enactments. The use of certain types of trap is to be prohibited altogether; the use of mechanically propelled boats or of aircraft is to be prohibited as an aid to killing or capturing birds; the capture of birds on highways, commons, and public places is to be prohibited; the killing or capture of birds on Sunday is to be prohibited; and the catching of birds alive is to be prohibited except under licence granted by the competent local authority. Lastly, the liberation of imported birds is to be permissible only with the authority of the Secretary of State, a wise provision aimed at the prevention of interference with the balance of nature.

The great advance in legislation of this kind which is marked by this Bill, however, lies in its application not only to offenders caught red-handed but also to all persons found in possession of birds, parts of birds, nests, or eggs which may be presumed to have been illegally taken. The onus of proof is to be thrown wholly on the possessor in the case of birds, nests, or eggs in Category I. and nests or eggs in Category II., and also in other cases during the whole of the close season except its first fortnight. Further, every taxidermist and dealer is to be compelled to keep a register giving all particulars of specimens passing through his hands which come under Categories I. and II. If this measure becomes law we may therefore hope to see an end of the scandal that the skins and eggs of some of our rarest and most strictly protected birds may be seen openly displayed in the taxidermists' windows or publicly advertised in the catalogues of dealers. Similarly, it will become an offence to sell or possess "plovers' eggs" after April 20 (allowing five days' grace from the beginning of the close season specially determined as regards the taking of these eggs).

The Secretary of State is to be empowered to grant special licences to kill or take protected birds or to take their eggs or nests either for scientific purposes, for the protection of crops, property or fisheries, or for other special reasons. The potential exemption from the law in favour of scientific purposes is a useful new provision, but it is to be hoped that the power will be very sparingly exercised in view of the great amount of useless collecting, especially of eggs, which masquerades under the name of science.

The Capillary Blood-Vessels.

The Anatomy and Physiology of Capillaries. By Prof. August Krogh. (Silliman Memorial Lectures.) Pp. xvii + 276. (New Haven: Yale University Press; London: Oxford University Press, 1922.) 13*s*. 6*d*. net.

EVERY cell of the body is brought into material relationship with all other cells in virtue of the existence of a common medium, the blood, which is maintained in constant circulation throughout the body. Substances absorbed into the blood from the exterior, either through the external or internal surfaces of the body, are thus brought round and presented to every cell, to be taken up or rejected according to the needs of the latter. In the same way the products of the chemical changes occurring in any cell are distributed to all other cells, so that the blood represents the internal environment integrating the metabolic activities of all parts of the body. The interchange between blood and tissues takes place only in the capillaries and smaller veins, so that we may say that the whole vascular system—heart, arteries, and veins—exists to ensure an adequate passage of blood through the capillaries. It is therefore rather surprising that the physiology of the capillaries has been comparatively neglected until the last few years. There have been isolated observations with regard to their structure and contractility and the properties of their walls. Some twenty-five years ago, when the question of lymph production and absorption was brought into prominence by the researches of Heidenhain, the functions of the cells forming the capillary walls were hotly debated, but after a few years, interest in the matter died down, and physiologists failed to appreciate or to follow up the many other problems concerning the capillaries which were implicit in the problems of lymph production.

By a study of injected specimens, or of the circulation in the lung or web of the frog, it can be seen that an arteriole breaks up into a large number of capillaries, each of which may have a diameter approximating to that of the arteriole. The relations in this part of the circulation have thus often been compared to those in a narrow stream flowing into a lake, and it has been tacitly assumed that the circulation through the capillary network as well as the state of dilatation

of the vessels forming this network were simply functions of the general blood pressure driving blood through the arteriole and of the state of contraction of the arteriole itself.

In reading the views on the circulation which were general before the discoveries of Harvey, we are often filled with astonishment that men endowed with mighty intellects, like Leonardo da Vinci, could not see what seems to us so self-evident. It is difficult to comprehend how any one could dissect the heart and be familiar with the effects of wounds of different parts of the body and fail to perceive the meaning of the valves in the heart and the course of blood through this organ. Yet we ourselves every day are equally blind. It is self-evident that the colour, say, of the skin, depends not on the amount of blood in the small arterioles but on the fulness of the capillaries. Every one knows that the capillaries may be overfilled together with constricted arterioles, giving rise to blue cold skin, or that the capillaries may be less full but with a vigorous circulation through dilated arterioles, so that the skin is warm and of the normal colour. These two observations should be sufficient to show that the state of dilatation of the capillaries is not dependent only on the condition of the arteries. Even a lifetime devoted to science and research seems incapable of preventing us from accepting familiar appearances without trying to understand them. It is not until some one puts a definite question and our curiosity is aroused that we become aware of a problem to be solved. In science it is the question that matters: the solution can always be found.

The recrudescence of interest in the capillaries occurred suddenly, many observers being led to the subject by the most diverse considerations. Among these Ebbecke was perhaps the most directly interested in the capillaries themselves. H. H. Dale was led to infer independent changes in the capillaries from his observations on the effects of histamine. Krogh, continuing his researches on respiration, found it necessary to consider the volume of the capillary circulation required for supplying sufficient oxygen to the working tissues. Then, during the War, the committee appointed by the Medical Research Council to investigate the causation of surgical shock was led to ascribe the main part in the production of this condition to the abnormally dilated state of the capillaries. Thus from all sides the attention of physiologists was focussed on these structures. As a result we can boast of a very large accession to our knowledge not only of the capillaries but also of the factors determining the supply of blood to the tissues under varying conditions.

The volume under review, by the man who has perhaps done more than any single physiologist to advance our knowledge of the capillaries, not only gives a connected account of our present knowledge, but also adds to this a large amount of original work which has been previously unpublished. Prof. Krogh starts with an account of the anatomy and distribution of the capillaries. He shows that in muscle, for example, the number of capillaries which are open varies from time to time according to the activity of the muscle. In a muscle of the horse there are about 1350 capillaries in every square millimetre of transverse section. The transverse section of an ordinary pin is about half a square millimetre. We get an idea of the extraordinary subdivision of the blood supply within a working tissue when we consider that within a structure of the size of a pin there are 700 parallel tubes carrying blood, in addition to about 200 muscle fibres. In smaller mammals, such as a guinea-pig, the maximum number of capillaries per square millimetre is about 4000. This means that an enormous surface of blood is available for interchange to take place with the tissue cells. Krogh makes the following calculation: "Supposing a man's muscles to weigh 50 kilograms and his capillaries to number 2000 per square millimetre, the total length of all these tubes put together must be something like 100,000 kilometres or two and a half times round the globe, and their total surface 6300 square metres."

The author makes a plea for further work on these lines. There is a rich field for the anatomists in such quantitative anatomy, especially if the problems attacked are chosen according to their importance for the normal functions of the body.

Krogh then shows by various means that the capillaries are endowed with an independent power of contractility, and that this is due to the existence of special kinds of muscle cells present in all capillaries and apposed to the outside of their thin endothelial wall. It is noteworthy that these cells were described so long ago as 1873 by Rouget, but the observation was disregarded and soon forgotten.

In the following lecture the author deals with the innervation of the capillaries. Here again histologists long ago described a rich supply of fine non-medullated nerve fibres, but the physiological significance of these fibres has been revealed only in the last few years. The innervation of the capillaries is of two kinds. In most cases stimulation of the sympathetic provokes contraction. They are also under the influence of the antidromic impulses, which cause dilatation, and, as Bayliss has shown, can be excited in the sensory fibres of the posterior root

and peripheral nerves. It seems that at their periphery these sensory fibres form a branching network, which in some of its functions resembles the diffuse superficial nerve network so widely distributed in the invertebrata. Stimulation of the surface, especially if painful, causes a dilatation of capillaries and small arteries which spreads for some distance round the stimulated spot. There is no evidence that nerve cells are involved in this local reflex, which is therefore regarded as an 'axon reflex.' The redness produced by the application of mustard to the skin is an example of this kind of reaction. If pronounced it may go on to the production of increased transudation of fluid from the affected capillaries and to the appearance of a blister.

After dealing with the local response of the capillary wall to mechanical and chemical stimulation, Krogh proceeds by a series of carefully thought out experiments to the demonstration that, throughout life, the calibre of the capillaries is regulated by some diffusible substance present in the blood, and he tracks this substance finally down to the internal secretion of the posterior lobe of the pituitary body. Perfusion of a frog's limb with Ringer's fluid causes wide dilatation of the capillaries and production of dropsy. If, however, the minutest trace of the pituitary hormone is added to the perfusion fluid, the capillaries retain their normal size and no œdema results.

Having arrived in this way at a knowledge of the factors affecting the calibre of the capillaries and the volume of the flow through the capillaries in any part, Krogh then proceeds to consider the bearing of these results on the main functions of the capillaries, namely, the nutrition of the tissues, the giving off of oxygen from blood to tissue cells, the taking up of carbon dioxide, the exchange of dissolved substances, and the production and absorption of lymph. In a final chapter he deals with various miscellaneous questions closely associated so far as regards their mechanism, such as the production and absorption of intra-ocular fluid, the condition known as surgical shock, and the causation of weals and urticaria under the influence of poisons or in persons of the so-called 'vaso-neurotic' disposition.

It is impossible within the limits of a review to do justice to the wealth of new facts and points of view brought out in the course of these lectures. We feel from the outset that we are starting on a voyage of exploration with the author. In every new step our curiosity is aroused before we are presented with the solution. At the same time we are conscious of the intellectual dangers which beset the explorer in these fields. The author states: "The problems of physiology are so complicated that, to put it tersely, one cannot expect to be able to reason correctly from the facts for more than five minutes at a stretch"—a healthy state of mind and very similar to that expressed by Harvey when he says that he "began to think with Frascatorius that the movement of the heart was known to God alone." But such difficulties and dangers only add to the joy of the chase, and we read the book with somewhat the same fascination and interest that our forefathers must have felt when presented with the immortal treatise of Harvey.

The book is written clearly and simply. We can conceive no better book to put into the hands of a student to arouse his interest in the advancing fringe of physiological knowledge and to acquaint him to some extent with the joy and spirit of research.

(1) FOR many years back the published researches of G. N. Lewis and his collaborators have occupied a prominent place in the branch of science dealing with the application of thermodynamics to the solution of chemical problems. The book now under review, of which he and his co-worker, Merle Randall, are joint authors, collects and summarises these researches and places them in position in the general framework of thermodynamics. For this alone all interested in matters pertaining to physico-chemical theory would owe them thanks, but the debt is increased by the fact that no better account of modern chemical thermodynamics than appears in this book can be placed in the hands of advanced students.

The treatment, while remaining in some ways conventional, has an individual freshness which makes the volume much more readable and interesting than most treatises on the subject. The material is divided into three parts, the first treating of the foundations of thermodynamics, the second dealing with the special methods of applying the fundamental principles to chemical problems, and the third being devoted to a systematic consideration of the data of thermodynamic chemistry. As might be expected, the notions of

"fugacity," "escaping tendency," and "activity" play a great part in the authors' development of the thermodynamics of simple substances and solutions, both non-conducting and electrolytic. The galvanic cell and single potentials receive adequate treatment, and a long chapter is devoted to the Third Thermodynamic Principle and the Chemical Constants of Nernst. The chapters of the last section of the book deal systematically with the entropies or free energies of chemical elements and their chief compounds. It is in this section that the book differs essentially from all its predecessors. So far as data are available they are utilised to calculate the changes in free energy attending important chemical reactions. Thus, under the heading "water" there is discussed the free energy of formation of water (*a*) from measurements of its dissociation at high temperatures, (*b*) from the dissociation of silver oxide, (*c*) from the dissociation of mercuric oxide, and (*d*) from the equilibrium of the Deacon process. Based on the mean of the independent and concordant values obtained by these four methods, a final value for the free energy of formation of liquid water is given. The free energy changes in the vaporisation and solidification of water are discussed, and finally the free energy of formation of the hydroxide ion. A table is given of standard free energies of formation at 25°, together with instructions for its use and numerous examples.

While admiring the skill and clearness with which many abstruse conceptions are brought before the reader, we must direct attention to a statement which, if not exactly erroneous, is certainly misleading. The authors (p. 115), after defining change of entropy, say: "Thus entropy has the same dimensions as heat capacity, and may be expressed in calories per degree." Again (p. 144), calculating the difference of entropy between solid and liquid mercury at the constant temperature of its freezing-point, they say: "We have from Equation (1) $\Delta S = \Delta H/T$. If ΔH is the heat of fusion of one mol, namely 560 cal., and T is 234·1, we may write $\Delta S_{234 \cdot 1} = 560/234 \cdot 1 = 2 \cdot 39$ cal. per deg." Surely there is an essential difference between $\Delta H/\Delta T$ (heat capacity) and $\Delta H/T$ (entropy); and surely the words "per degree" imply that the temperature is variable, which is here not the case. Such minor lapses as the above are most infrequent, and we have nothing but praise for the book in general. The formulæ are clear, and the notation employed is consistent, although not always in accordance with the table of International Physico-chemical Symbols. A good index is a valuable adjunct to the volume.

(2) A cordial welcome will be given to the new edition of Nernst's "Theoretical Chemistry." Written by one who is a master of research and of exposition, the book has been the guide of many generations of serious physico-chemical students, and nothing better of its type is ever likely to appear. It is not everywhere easy reading, but close study of the text will always provide an ample reward. In the present edition the chapters on radioactivity and the theory of the solid state have been largely rewritten, and sections have been added dealing with the structure of atoms and the application of X-rays to the determination of molecular dimensions. The translator, by not following the German text too slavishly, has provided a version which is both readable and accurate, though finer shades of meaning are not always faithfully reproduced: thus (p. 767) *Zusammenbacken* is translated by *solidification*, (p. 885) *Wechselwirkung* by *conversion*, (p. 874) *höchstwahrscheinlich* by *certainly*. It might be worth the attention of the publishers to consider the use in future editions of italic letters for algebraic quantities, as in the German original, instead of Roman letters, as in this translation. The former catch the eye better and facilitate reading.

A Scientific Introduction to Biology.

Elements of Plant Biology. By A. G. Tansley. Pp. 410. (London: G. Allen and Unwin, Ltd., 1922.) 10*s.* 6*d.* net.

TO write a text-book of botany is nowadays no easy task. The subject itself has grown in many directions, and it demands some knowledge of all the main branches of science as a preliminary to tackling even the simpler problems with which it confronts the student. A book intended for use in junior classes in a university must obviously then be the outcome of careful sifting and artistic synthesis of raw material if it is to be of any real value, and especially is this true when the demands of the student of medicine have to be satisfied. Botany, properly presented, forms perhaps the best introduction to biology for the purpose of the medical student, but how often when he has asked for bread has he been put off with unprofitable and altogether unattractive stones!

A modern introduction to botany ought to aim at affording some real insight into the working mechanism of life, and to make it possible to understand, at any rate, the more outstanding features of that mechanism as it behaves when in action. The machinery is vastly complex, and we have only been able as yet to certainly know fragments of the factory-processes that go on so swiftly and so smoothly within the plant cell. But it is possible, even now, to pick out and illustrate those processes by judicious selection of material, and so vividly to portray them in their larger outlines.

In his "Elements of Plant Biology" Mr. Tansley has certainly achieved a great measure of success in discharging a task beset with difficulties, and his book deserves to be widely read, for it possesses a certain indefinable, but none the less real, quality of distinction. The author has thought out his subject-matter well, and he has succeeded better, we think, than any of his predecessors in giving, on elementary lines, a clear and comprehensive account of the main features of plant life regarded from a truly scientific point of view. His mode of exposition is clear and his choice of material admirable, and thus, with remarkable freedom from esoteric technicality, he has produced a volume that really does provide the student with what will stand him in good stead, no matter what branch of biology he may ultimately elect to follow up. Furthermore, the book may be recommended with no less confidence to those who want to know something of some of the most important tendencies in modern biology, even if their main interests happen to lie in quite other fields.

The opening chapters touch briefly, and very clearly, on those physical and chemical aspects of the subject which are so essential to any real understanding of the living organism. The cell, its structure, its modes of reproduction, and so on, is sufficiently described, and its marvellous variety, both in form and development, is illustrated by well-chosen examples, special prominence being accorded to essentials, whilst details which, for the purpose of this book, are of less moment have been wisely passed over. A good account is then given of the leading and most generally interesting facts of structure and function as displayed in the various main groups of the vegetable kingdom, the whole treatment being so worked out as to enable the reader to obtain a comprehensive, if elementary, grasp of the chief evolutionary story of plants.

It is possible that a chapter on genetics might lend more completeness to this admirable volume; but with the object the author had more especially before him when writing it, possibly the omission was deliberate. Moreover, he does, in his closing chapter, briefly discuss the larger aspects of evolution, and the present writer especially welcomes the expression of opinion that "there is no bar to the appearance of characters which are of no *use* to the organism, nor even of characters which are disadvantageous to it, *provided they do not handicap the organism sufficiently to destroy its chances of continued existence*." This sentence (the italics are the author's) is in real accordance with the facts as they may be gathered from a study of plants actually growing in the open, and it represents a point of view which it is well to emphasise in the face of much false doctrine based on fanciful teleology. Lucretius, regarding the matter from a somewhat different angle, has well said in his "De Rerum Natura" (iv. 834-5):

> Nil ideo quoniam natumst in corpore ut uti
> Possemus, sed quod natumst id procreat usum.

J. B. F.

Kamerlingh Onnes and his Laboratory.

Het Natuurkundig Laboratorium der Rijksuniversiteit te Leiden in de Jaren 1904–1922. Gedenkboek aangeboden aan H. Kamerlingh Onnes, Directeur van het Laboratorium bij gelegenheid van zijn veertigjarig Professoraat op 11 November 1922. Pp. iv+458. (Leiden: Eduard Ijdo, 1922.)

AT a recent lecture given in London by Prof. H. A. Lorentz, Sir William Bragg made the happy remark that Holland, per square mile of its land—and water!—produced more eminent physicists than any other country. Amusing, and true. The appearance of the volume with the above title is another reminder of how true it is. Surely it is almost, if not quite, without precedent that it should fall to the lot of the same scientific investigator to have his work commemorated twice during his lifetime. Yet this is what has happened here. In 1904 there appeared a book, produced by his colleagues, to celebrate the twenty-fifth anniversary of the bestowal of the title of doctor on Heike Kamerlingh Onnes. The name of that book is identical with that of the present one, except for the dates—1882 to 1904; and in its introduction, if a free translation from the Dutch may be permitted, its purpose is described as "a review of what by him—through his inspiration, under his direction, by means of the apparatus he has assembled, and from his learning—has been added to the advancement of science."

It has appeared to the committee responsible for the new commemoration—Prof. Zeeman being the chairman and Prof. Lorentz himself a member—that the occasion would be served best by bringing out what Prof. Lorentz calls a "second edition," dealing with the work in Prof. Onnes' laboratory during the period 1904–1922, a period which includes the successful liquefaction of helium in 1908 and the well-known subsequent advances in the attainment and use of low temperatures. The cryogenic laboratory at Leyden has for some years become "an international institution for scientific investigations at very low temperatures"—a fact made evident by the names of those who have worked there and contributed papers to this volume. The description given by Dr. Crommelin indicates what a magnificent and well-organised laboratory it now is; but, until the enlarged building was completed and opened in January

1921, lack of space apparently added great difficulties to the work, and it is significant of the capacity of Prof. Onnes and those who have laboured with him that the output of valuable results has been so profuse. The new laboratory is indeed a fitting monument to a great man.

The book is, appropriately enough, mainly in Dutch, but each contributor has, in fact, written in his own language. Prof. Lorentz has contributed the foreword, in which he pays glowing tributes to his colleague. There are five chapters, of which the first contains articles descriptive of the laboratory itself. The late Prof. Kuenen describes the international character of the work, and Dr. Crommelin, upon whom seems to have fallen a lion's share of the labour of production, gives a very complete picture of the buildings, equipment, apparatus, and methods of work. Each of the four remaining chapters deals with a special field in which low temperatures have been applied. W. H. Keesom and E. Mathias, among others, contribute papers on thermodynamic investigations with gases. Researches on magnetism at low temperatures, carried out by himself and Prof. Onnes, are described by P. Weiss. Chapter IV. is entitled "Investigations in Optics, Magneto-optics, and Radioactivity," and contains papers by Zeeman, Jean Becquerel, Ehrenfest, and Mme. Curie. The last chapter, which refers mainly to the super-conductivity displayed by metals at very low temperatures, and contains a paper by Einstein, includes also reviews of results connected with the Hall effect, piezo-electricity, and other electric phenomena. There are numerous illustrations and diagrams; a few sketches appear also, including a frontispiece portrait of Prof. Onnes, drawn it is not clear whether by himself or by a near relative of the same name.

It is altogether a book worthy of the occasion; it properly impresses one with the exceptional greatness of the work and of the man. Strictly, of course, it is a tribute from his colleagues and students, but it is one in which, without distinction of nationality, we should all be ready to join unreservedly.

Thirty Years of Public Health Work in Manchester.

Observations on the History of Public Health Effort in Manchester. By Dr. James Niven. Pp. vii+230. (Manchester and London: John Heywood, Ltd., 1923.) n.p.

THE retirement of Dr. James Niven, the medical officer of health of Manchester, has led to the preparation by him of an intensely interesting account of public health effort in Manchester since 1894, when he first became responsible for the official health work of this city. The story is one which will be read with interest and admiration, not only by those colleagues in the public health service who for many years have looked to Dr. Niven for light and guidance in the application of science to preventive medicine, but also by many others who know that sanitary progress in this period has been as great as, or even greater than, the progress in life-saving surgery.

Here we can merely direct attention to a few salient points, advising all who can obtain a copy to study the report in detail.

In the stride forward of preventive medicine, there has been a tendency to have regard solely to specific infection as a source of disease; but Dr. Niven wisely, in the outset of his report, expresses the well-founded view that by far the most important influence which has governed the improvement of the public health in Manchester, apart from economic conditions, has been the removal of organic filth, whether within or without the habitations of the people. The story of improvement in this respect is vividly told, the region of least success being that of emission of smoke from chimneys.

The general result of all the reforms achieved, as shown in vital statistics, comparing the period 1891–95 with 1916–20, is that the general death-rate has declined 40 per cent., typhus fever is extinct, the death-rate from enteric fever has declined 92 per cent., diarrhœal diseases 74 per cent., the rate of infant mortality 44 per cent., and pulmonary tuberculosis 42 per cent. The story as regards enteric fever and diarrhœa is especially impressive. The abolition of pail-closets, the reform of stable-yards, the aid furnished by bacteriology in the diagnosis of enteric fever, the recognition of carriers and shell-fish as important sources of infection, and steady action against the domestic fly, have all borne their share in securing the vast improvement which is recorded.

Dr. Niven was the pioneer of administrative control of tuberculosis in Great Britain, and his review of progress made is especially important. In defending direct action against the disease as distinguished from indirect action against slum dwellings, he holds the balance very fairly. He agrees that history and experience alike point to the relief of economic pressure as the most powerful weapon in combating tuberculosis; but attack solely from this point of view erroneously assumes that economic conditions can be altered at will. This being so, there is no excuse for neglecting direct action founded on an intimate knowledge of the disease. There is the further point that we are concerned with a vicious circle. Not only does poverty favour tuberculosis, but it is itself a poverty-

making disease, some 40 per cent. of existing poverty having been estimated to be due to it. In a full discussion of housing difficulties, Dr. Niven points out the impossibility of securing satisfactory housing in central districts on economic lines, and in this connexion suggests that the necessary expenditure might be diverted from what is wasted on alcoholic drinks. He asks, "Can there be any doubt that the liquor trade paralyses the hands of the social reformer and keeps the people poor?"

Only a few of the important subjects discussed in this valuable review of public health progress have been mentioned; but we trust that the attention now directed to it may lead to its study by many who at present realise inadequately the vast strides already made in the prevention of disease and in the improvement of the public health.

The Ichthyosaurians.

Die Ichthyosaurier des Lias und ihre Zusammenhänge. Von Friedrich von Huene. Pp. viii + 114 + 22 Tafeln. (Berlin: Gebrüder Borntraeger, 1922.) 25*s*.

BARON F. VON HUENE is well known by his numerous writings on fossil reptiles of strange and rare types which are represented by more or less fragmentary specimens. He has now turned his attention to the comparatively familiar ichthyosaurians, of which, perhaps, more nearly complete skeletons occur in museums than of any other reptiles. As he remarks, the osteology of this group is now rather well known. He therefore devotes his work chiefly to a definition of the species, with an attempt to arrange them in genera and to determine their relationships. He has made many new observations on the specimens from the Lias of south Germany, of which he publishes important illustrations. In this research he acknowledges especially the valuable help of Dr. Bernhard Hauff, of Holzmaden, whose fine preparations of Liassic reptiles and fishes are now scattered through many museums.

Baron von Huene adopts the usual classification of the ichthyosaurians into those with the fore paddles broad and those with the paddles long and narrow. He also considers that these two groups remain distinct from the beginning to the end of the career of these marine reptiles. He recognises and names more genera, however, than have hitherto been supposed to occur, and his taxonomy is not likely to meet with general approval. Ichthyosaurus, for example, altogether disappears as a generic name; and other generic names already exist having priority over some of the new names proposed. The taxonomy is indeed the least acceptable part of the work.

The stratigraphical distribution of the ichthyosaurians in the Lias of south Germany is shown in a table, and it would be interesting to make an equally detailed study of the distribution of the species in the several zones of the Lias in England. Except the typical species of Ophthalmosaurus from the Oxford Clay, the later ichthyosaurians are still known only by comparatively fragmentary specimens.

The author concludes his work with a large table of outline sketches to illustrate the evolution of the ichthyosaurians from their first appearance in the Middle Trias to their disappearance in the Upper Cretaceous. At the beginning he places the small Mesosaurus, of Permian age, which he considers may be related to the semi-aquatic primitive ancestor of the whole group, which still remains unknown. The Triassic forms are represented as long-bodied, with the backbone only slightly bent downwards where a small caudal fin arises. The caudal fin is completed before the end of the Liassic period; and it becomes more effective as a propeller by the shortening of the caudal pedicle in the Upper Jurassic forms. The only Cretaceous species sufficiently well known for restoration is represented as again slender, with a comparatively small though complete caudal fin.

The volume is excellently printed and illustrated, and we commend it to the notice of all students of vertebrate palæontology. A. S. W.

Our Bookshelf.

Die steinzeitlichen Stationen des Birstales zwischen Basel und Delsberg. Von Fritz Sarasin. Prähistorischer und anthropologischer Teil von Fritz Sarasin. Paläontologischer Teil von H. G. Stehlin, unter Mitwirkung von Th. Studer (Aves). Mit 32 Tafeln und 20 Textfiguren. Neue Denkschriften der Schweizerischen Naturforschenden Gesellschaft. Band liv. Abh. 2. (Basle, Geneva und Lyons: Georg und Co., 1918.) n.p.

THE above volume, only recently issued though dated 1918, contains some 290 pages of text, with 32 full-page illustrations at the end. There are also some 20 figures in the text giving sections, maps, and the like. A full and careful account of a number of diggings just south of Basle is given, including a description not only of the archæological finds, but also of the mammalian and bird remains. The whole forms a useful addition to our knowledge of prehistoric times in this region.

The first part of the volume is devoted to a description of finds from a number of caves. The industries recognised are Neolithic, Azilian, and Magdalenian. Owing to the area being outside the region of glaciation, the determination is done on purely typological grounds. A Neolithic burial (with skeleton complete) was unearthed, and a full account is given. In one instance "painted pebbles" were discovered in an Azilian layer. It is interesting to find these typical Azilian objects so far north. There is evidence of Azilian culture as far

north as West Scotland, but hitherto "painted pebbles" have only been found farther south. The latter part of the book is concerned with an account of some open-air Neolithic stations. The whole is completed by the inclusion of a very full bibliography, referring both to the archæology and to the palæontology.

The authors are to be congratulated on their explorations and on the publication—especially on having managed to include so many and such excellent plates. The area under discussion is of course restricted, but it is exceedingly important that the results obtained in various diggings should be carefully published, and not, as is, alas, so often the case, be either not published at all or merely noted briefly in some obscure review. The finds described in the above work are preserved in the museum at Basle. M. C. B.

The Practical Applications of X-rays. By Dr. G. W. C. Kaye. Pp. viii + 135. (London: Chapman and Hall, Ltd., 1922.) 10*s.* 6*d.* net.

THIS book is based largely on a course of Cantor Lectures given by the author, and is primarily concerned with the many practical applications to which X-rays are put at the present time; this term is, however, not meant to include their medical applications.

Rather more than one-half of the book is devoted to a description of the methods of production of X-rays and of their measurement; such a liberal proportion of space will generally be welcomed by those seeking to apply X-rays for themselves. During the War, X-rays were used successfully to detect flaws in aeroplane parts, and the author shared very largely in this work, of which some good illustrations are shown. The main industrial application may perhaps be said to be in the examination of metal castings, and the recent technical developments, whereby X-rays of very short wave-length may be obtained, should see a widening range of application here.

X-ray examination shows some very striking differences between ancient and modern pictures; these differences are mainly due to the pigments and primers employed by the artists; present-day pigments are not nearly so opaque to X-rays as the metallic pigments used by the earlier painters. Some illustrations from the work of Heilbron will convey sufficiently well to the expert the assistance he may expect from the radiologist in detecting the work of the vandal.

The volume contains in one appendix the two memoranda which have been issued by the X-ray and Radium Protection Committee on methods of safety, and in a second appendix a useful list of definitions of terms in common use in X-ray and electro-medical literature.

Principles and Practice of X-ray Technic for Diagnosis. By Dr. John A. Metzger. Pp. 144. (London: H. Kimpton, 1922.) 14*s.* net.

THE author's aim is "to put into the hands of the student and operator a formula on which to base his work in order that he may obtain better results and thus be able to reach a more correct diagnostic interpretation."

We must confess to a failure in finding the "formula." The book opens with a glossary of terms and this is scarcely reassuring; for radiography we read "same as skiascopy," which is not defined; X-rays are said to be rays of unknown quantity; tension is defined as the tendency of electricity to overcome resistance.

On the second page of the first chapter the author discusses the use of gas and Coolidge tubes, but we are left wondering at what is meant by the following statement: "The difference between the tubes used with the high-frequency machines and the induction coil is one of the vacuum, and the additional cathode of the former to care for the inverse, while the difference between those for the induction coil and the transformer is that of a heavier target construction and lower vacuum of the one to care for the additional voltage and absence of an inverse."

The book is profusely illustrated, mainly in order to show the various positions of the patient which the author advises for different diagnostic purposes. Many of these are quite unnecessary, and three of them are duplicated in the text.

A Text-book of Intermediate Physics. By H. Moore. Pp. ix + 824. (London: Methuen and Co., Ltd., 1923). 22*s.* 6*d.* net.

THIS is a very complete text-book for intermediate students in universities. It is well printed, has many original illustrations, and is provided with an exceptionally good index of thirty-nine pages. Block type is used for the principal laws and conclusions, so that revision of his work on the part of a student is facilitated. The author has, however, unfortunately reproduced a number of the mistakes and incomplete statements of his predecessors. He confuses surface energy and surface tension, and on p. 149 he speaks of the weight of the liquid below the meniscus in a capillary tube being supported by the surface tension. He devotes more space than is desirable to old and discarded methods, *e.g.* Laplace and Lavoisier's expansion apparatus, p. 173, and specific heat apparatus, p. 218, while no information is given as to how the expansion coefficient of a gas is calculated from observations with accurate apparatus, p. 191. On p. 254 the saturation vapour pressure over a solid is incorrectly shown. The part on light is good, but there seems no reason for omitting old sight from the list of defects of the eye on p. 458. There appears to be no mention of the magnetic circuit, and the diagrams of dynamos on pp. 739 and 741 may account for the necessity of silence on the subject.

Abriss der Biologie der Tiere. Von Prof. Dr. Heinrich Simroth. Vierte Auflage, durchgesehen und verbessert von Prof. Dr. Friedrich Hempelmann. Teil 1. Entstehung und Weiterbildung der Tierwelt. Beziehungen zur organischen Natur. (Sammlung Göschen Nr. 131.) Pp. 147. (Berlin und Leipzig: Walter de Gruyter und Co., 1923.) 1*s.*

THIS is a revision of Simroth's "Sketch of the Biology of Animals," and a very interesting little book it is. We do not think that the text corresponds particularly well with the sub-title, which might be translated "Rise and Progress of the Animal Kingdom: Relations to Organic Nature"; and in the catalogue these are the titles of two separate volumes. But that is a trivial detail. The little book before us deals mainly

with the following subjects—the relations of animals to gravity and their locomotion in various media; light, colour, and luminescence; equilibration, hearing, and touch; chemical influences; the influence of heat and cold; animal electricity; and respiration. This is a lot to cover in 150 small pages, but we are bound to say that the treatment is very effective. The chapters are simply illustrative, and thus they remain interesting. Most of the illustrations are fresh.

Origine de la vie sur le globe. Par Julien Costantin. (Bibliothèque de Culture générale.) Pp. 192. (Paris: Ernest Flammarion, 1923.) 4.50 francs net.

The problem of the origin of organisms upon the earth continues to attract and to defeat the inquisitive spirit. Prof. Julien Costantin discusses it in various aspects: Had living creatures a beginning at all? If they had, what were the first organisms like? Did plants come before animals? Is there any clue in the so-called "life of crystals"? He also inquires into the meaning of animate organisation, the importance of colloids, the chemistry of the cell, the puzzle of cell-division, the processes of growth and development.

The chapters are all careful and clear, but they do not lead us to any solution. The author concludes that there must have been pre-Cambrian spontaneous generation, that it is very improbable that it ever occurred again, that there is no hint of its occurring now, that green algæ were the first organisms, and that there is nothing to show that they were preceded by bacteria, that the hypothesis of cosmozoa only shelves the problem, and that their hypothetical arrival on the earth should have been followed by several distinct lines of evolution, which is not what the facts indicate. To expect to effect the synthesis of living matter in the near future is "perfectly ridiculous."

University of Oxford: Institute for Research in Agricultural Economics. An economic survey of a rural parish. By J. Pryse Howell. Pp. 31. (London: Oxford University Press, 1923.) 1*s*.

This little survey, extending to 25 pages only, is quite useful as an example of the kind of inquiry that could well be made in many more of our country parishes. We are told nothing of the location of the particular parish, not even its county, and the work loses much of its value in consequence. But the survey gives a picture of a village, presumably in Wales, where the houses are let at annual rentals of 25*s*. upwards, and where the inhabitants apparently produce most of what they need for themselves, since the sales from the farms work out to about £50 per annum only per person employed. It is interesting and should prove instructive to any rural or urban dweller interested in the human side of agriculture.

Tychonis Brahe opera omnia. Edidit I. L. E. Dreyer. Tomi quinti, fasciculus posterior. Pp. 217-343. (Hauniae: Libraria Gyldendaliana, 1923.) n.p.

This is a supplement to vol. v. of Tycho's collected works. It contains several examples of Tycho's observations of the sun and planets, and his discussion of them, assuming that the sun (the centre of the planetary motions) itself goes round the earth. These will always remain classic, from the part they played in establishing Kepler's Laws, and later Newton's law of gravitation.

A map of Huen is reproduced.

The table of longitudes and latitudes reminds us how inaccurate the knowledge of longitude was in Tycho's time; for example, Alexandria is placed 36° east of London.

The volume closes with twenty-five pages of useful editorial notes. A. C. D. C.

Scientific Method: an Inquiry into the Character and Validity of Natural Laws. By A. D. Ritchie. (International Library of Psychology, Philosophy, and Scientific Method.) Pp. viii + 204. (London: Kegan Paul and Co., Ltd.; New York: Harcourt, Brace and Co., Inc., 1923.) 10*s*. 6*d*. net.

Mr. Ritchie's book being a dissertation for the examination for a fellowship at Trinity College, Cambridge, is primarily designed to prove the extent and depth of the writer's reading. It leads us to hope much from Mr. Ritchie when he no longer needs credentials. The main scientific value of the book is perhaps that it reveals the type of mind the present Cambridge teachers are nurturing and the direction of research they are encouraging.

Traité de Psychologie. Par Prof. Georges Dumas. Tome 1. Pp. xiv + 964. (Paris: Félix Alcan, 1923.) 40 francs net.

The work under notice partakes more of the nature of an encyclopædia of psychological science than of a treatise on psychology. It is a reminder of the exuberant growth of the subject in our own time. It was designed by the late Théodule Ribot, and his preface is retained, but the present edition is under the direction of Prof. Georges Dumas, and he has secured as his collaborators a number of most distinguished workers, every one eminent in some branch of psychological science.

The Amateurs' Book of Wireless Circuits. By F. H. Haynes. Pp. 107. (London: The Wireless Press, Ltd., 1923.) 2*s*. 6*d*. net.

The amateur radio engineer will find Mr. Haynes's little work most instructive. The author begins with the simplest possible circuits and then introduces elaborations step by step until he arrives at many of the complicated arrangements used in practice. Standard symbols are employed and the diagrams are beautifully clear, so the gradual evolution of the systems can be very readily followed.

Questions and Problems in Chemistry. By F. L. Darrow. Pp. vii + 177. (London: G. Bell and Sons, Ltd., 1923.) 3*s*. 6*d*. net.

This book consists of a large number of very simple questions on chemistry, and may be found useful to teachers in schools. It is, however, more adapted for use with an American text-book, and adopts American spelling—"sulfuric," etc. The examination papers at the end are American, and in many ways the book will not fit in with English school methods.

Letters to the Editor.

The Editor does not hold himself responsible for opinions expressed by his correspondents. Neither can he undertake to return, nor to correspond with the writers of, rejected manuscripts intended for this or any other part of NATURE. *No notice is taken of anonymous communications.*]

Light and Electrons.

SIR OLIVER LODGE, in his survey of the problems connected with Ether and Electrons (NATURE Supplement, August 4), propounds the interesting question: "Does light generate an electron?" The hypothetical conversion of radiation into matter may, as he points out, accord with observed results as to the photo-electric emission of electrons. In particular the striking reciprocal relation between the energy of an electron and the energy of X-rays seems to justify his statement: "It is as if the same beta particle, that is, the same electron, had gone out of existence at one place, and been recreated at another, the intermediate link being constituted by specific radiation of a perfectly definite wave-length." Sir Oliver Lodge says further: "I know that the Bohr Theory of the Atom seems at first against these speculations. Electrons do appear to jump from one orbit to another, and thereby give out a certain quantum of energy. But this may be a supplementary, and not a contradictory statement."

In this connexion I should like to direct attention to a suggestion made by Prof. E. T. Whittaker in his paper on the quantum mechanism in the atom (Proc. Roy. Soc. Edin. vol. 42, p. 141, 1922). He points out that Bohr's theory of series spectra can be assimilated to the theory advanced in his paper in the following way. "In Bohr's theory let a negative electron E fall from an orbit of radius a_1 (position P_1) to an orbit of radius a_0 (position P_0). Now in the initial state of this system, which consists of the electron E at P_1, let us introduce two coincident electrons E' and E'' at P_0, one positive and one negative, so that they annul each other; and let us replace Bohr's conception of the fall of the electron from E at P_1 to E' at P_0, by the conception of the discharge of a condenser whose charges are E and E''; the discharge annihilates E and E'', and so leaves E' surviving alone at the end of the process, and is therefore equivalent to Bohr's notion of a translation of E to the position of E'."

The suggestion is easier to visualise if instead of the circling electrons of Bohr's theory we employ the stationary electrons obtained by introducing Langmuir's "Quantum Force" (*Phys. Rev.*, vol. 18, p. 104, 1921). The conception of the discharge of a condenser is not essential to the picture, and Sir Oliver Lodge may prefer to replace it by a mechanical vibration of the column of ether between E and E'', resulting in the production of what Silberstein has called a "light-dart." In speaking of the discharge of a condenser, as in speaking of the vibration of a medium, we are using figurative language, which is meant only to suggest an illustration of a process which is beyond the range of our experience.

One of the difficulties in Bohr's theory is to understand how the frequency of the radiation emitted in accordance with his fundamental frequency condition can be fixed as soon as the electron quits the first stationary state and before it has reached the final state. As Silberstein puts it: "Needless to say the founder of the new theory and his followers do not attempt to describe the mechanism of such an extraordinary performance, one, that is, that enables the atomic system to hit precisely upon the frequency required." Again in a recent letter Prof. C. G. Darwin (NATURE, vol. 111, p. 771, June 9) refers to the difficulty "that the quantum conditions determining the permissible Bohr orbits can only be explained physically by attributing to the electrons a knowledge of the future."

This difficulty—and the similar one which arises in connexion with absorption—seems to be diminished, if not entirely removed, by the suggestions put forward by Prof. Whittaker. On this view the emission of light originates not so much at the position P_1 as at the position P_0, where we may imagine an incipient crack in the ether developing under the influence of some external disturbance, say the approach of some other atomic system. There is here a suggestion of a discrete structure for the electromagnetic field (or ether) in the space surrounding an atom such as I have previously attempted to indicate in speaking of Faraday's magnetic lines as "Quanta."

In the present stage of the development of physics, when we seem forced to believe in two mutually contradictory theories of light (the undulatory and the corpuscular theory) at the same time, the wildest guess at a solution may be permitted. This must be my excuse for hazarding the suggestion that conceivably the "head" of the disturbance (derived from the negative electron E) spreads out as the light advances—the amount of spreading involved being a question requiring further investigation—whilst the "tail" (derived from a positive electron) retains to a greater extent its corpuscular character, and plays the part of one of Sir J. J. Thomson's "specks" as it follows the advancing wave-front. On this view absorption of radiation takes place when an electron grasps the light—in this revised version of Little Bo-Peep—by its "tail"!

The University, St. Andrews.

Continental Drift and the Stressing of Africa.

As one among many geologists who (so it would seem) would welcome proof of an hypothesis of continental drift, but who cannot accept Dr. Wegener's peculiar opinions with regard to it, I recognise that we owe a debt of gratitude to Dr. J. W. Evans for showing us an ingenious way out of some of the difficulties that Wegener, albeit unintentionally, demonstrates rather than removes; none the less, the views of Dr. Evans on this subject appear to be open to question.

Dr. Evans states (NATURE, March 24, p. 393) that "there seems reason to believe that Africa is in the main the centre of a region of tension, due to the outward drift of continental masses," which, as he points out, is explicable as "drift from a region of comparatively low gravity to one of higher gravity." Following Osmond Fisher and Pickering, Dr. Evans sees no objection to the view that the Pacific depression is the scar left by the separation of the moon from the earth—a phenomenon which Sir George Darwin attributed to tidal action—and is inclined to follow Prof. Sollas in regarding the African protuberance as an unsuccessful attempt on the part of the earth to produce another satellite.

The birth of the moon is a piece of extremely ancient history, and the consequent stressing of Africa, if indeed there be any such consequence, must have started as soon as the moon's mass was lost, or, in the event of excessive resistance of sima to sial—an unlikely event if the postulated circumstances of the moon's origin be correct—as soon as

the rise in temperature resulting from the blanketing of the sea bottom, by sedimentary deposits, in the neighbourhood of land masses became sufficient considerably to reduce the rigidity of the basic sima beneath the continental shelves. The great thickness of the earliest sedimentary strata suggests that this condition was attained in very remote geological times; and in view of the slow progress the continents would make by this process of drift, it would appear that the degree of separation now attained by these land masses may be taken to point to a similar conclusion, even though a liberal allowance be made for lateral collapse along the margins of the separated tracts. According to this view, tensional structures should be dominant throughout the geological history of Africa.

Of other African territories I will say nothing, but with regard to Uganda, which lies, be it noted, in the heart of the continent and between two great rift valleys, tensional structures are astonishingly absent, or, at any rate, difficult to find.

Deposited on a basement of crystalline rocks which represents, in all probability, a great accumulation of archaic sub-aqueous deposits intruded upon and largely metamorphosed by ancient acid magmas that have incorporated much of the sediments, is a very thick series of shales and sandstones (usually more or less altered) of great antiquity but of undetermined age. These are part of what we once called the Argillite series (a tentative term now abandoned, see Ann. Rept. Geol. Dept. Uganda, 1920, p. 10); they constitute what we now call the Ankolian system. These rocks have suffered much from folding and are sliced up by tremendous faults. Owing to the want of easily recognised horizons within the system, it is usually very difficult to demonstrate the nature of these faults. There can be little doubt, however, that they are essentially compressional structures, and in every instance where the fracture contacts have been seen they have revealed overthrust faults. After this great phase of faulting, the Ankolian beds have been thrown into a series of complicated domes, the eroded remains of which were first described by me as *arenas* (*loc. cit.* p. 14). Some of these have been the subject of careful study by Mr. A. D. Combe (Field Geologist, Uganda Service), who has mapped them in detail. It is quite certain that these do not give evidence of tension, but quite the reverse.

Above the Ankolian, and deposited unconformably upon that system, is the Mityana series, consisting of thick accumulations of sandstones and conglomerates; these, too, have suffered from faulting, but to a lesser degree than the Ankolian. The nature of these faults is as yet undetermined. The Ankolian and the Mityana series have together been thrust up by an enormous bathylith (the Mubendi bathylith), the denudation of which has exposed the newer granite: this does not look like tension. Deposits revealing plant-impressions, possibly of Jurassic age, which appear to be the next in order of sequence, have been located in eastern Uganda; they occur in a syncline of no great size: the significance of this structure is uncertain. No other tectonic movements are as yet known in this country until we come to (probably) late Cretaceous and Tertiary times, when we have the doming of Uganda (the Uganda-Congo dome lying to the west of the syncline of Lake Victoria, which itself lies to the west of the Kenyan dome or anticline). This structure can scarcely be interpreted as tensional; yet at the time of its inception continental drift, if drift there has been, should surely have been well advanced. The first structures of more than purely local significance that have been interpreted as tensional do not make their appearance until about middle tertiary times, though the action which they signify continued until much later: I mean, of course, the rift valleys, and even these, at any rate so far as their first inception is concerned, are more easily accounted for by compression than by its opposite.

Here, with the Semliki (Semaliki the natives call it) and the Congo rift-scarp to my left, the Toro-Bunyoro escarpment to my right, and the Ruwenzori range behind me, I write sitting on the evidence, as it were, that proves, perhaps for the first time conclusively, the tectonic origin of the Albertine depression, and demonstrates beyond all doubt the amazing fact that early man knew the lake when it stood more than 1000 feet higher than it does now. A thousand-foot head on Lake Albert is impossible to-day, and has been ever since the differential drop of the Bunyoro scarp not only released the pent-up waters of Lake Albert, but gave birth to the Victoria Nile that connects, through Lake Chioga, the great Nyanza with the Albertine depression. All this is, in my opinion, more easily accounted for as a necessary consequence of compressional activity than as the direct result of tension.

The tectonics of the rift is too big a question to discuss in a letter, but it may be noted that all the evidence that I have been able recently to obtain in Toro and in the Bwamba country supports the view, generally held, that Ruwenzori is an upthrust mass. It is directly connected with the rift but very probably pre-rift in age. Now there is evidence to show that since the inception of the Albertine rift the bottom of the valley has sunk by two distinct major movements well separated in time. The sinkage has been pivotal with a maximum downthrow to the north-east, as has the subsidence of Bunyoro. That which has remained firm and helped in marked degree to hold the sinking bottom of the rift valley is the great faulted upthrust of the Ruwenzori range: this does not look like tension anyway.

I am afraid that exception must be taken to Dr. Evans's use of the term rift as applied to the separation tract between drifting continents. Thus used, the term is most applicable, but it has priority in Prof. Gregory's usage, which, though it may be less apt, is now unalterable. E. J. WAYLAND.

Protozoa and Virus Diseases of Plants.

ATTEMPTS to discover the presence of a foreign organism in such diseases as tobacco-mosaic, tomato-mosaic, leaf-roll of potato, and numerous other similar infectious diseases have been the concern of botanists for many years. Although considerable knowledge has been gained as to the distribution of these diseases by insects such as Aphides, yet no causal organism has been observed with certainty, and the diseases have been classed accordingly as virus diseases. The failure to detect the presence of a foreign organism has naturally been a serious handicap in combating these diseases, many of which are of serious economic importance.

The appearance of a paper by R. Nelson entitled "The Occurrence of Protozoa in Plants affected with Mosaic and Related Diseases" (Agric. Expt. Station, Michigan, Bull. 58, 1922) is thus of great interest.

In this paper Nelson claims that protozoa are to be found in the phloem of plants affected by bean-mosaic and tomato-mosaic, and also in potato plants affected by leaf-roll, while such organisms are absent from the phloem of healthy plants.

Some of these organisms are described as possessing a single flagellum and an undulating membrane, others as biflagellate; their general resemblance to trypanosomes is also claimed.

When Nelson's paper was received in this country some few months ago, I was engaged in a study of the mosaic of hops, a disease probably to be classed as a virus disease. A search for protozoa similar to those described by Nelson was accordingly made in the phloem of hops thus affected. No such organisms were to be observed, but elongated deeply-staining structures having a marked resemblance to those figured by Nelson and described by him as protozoa were found, as shown in Figs. 1a, 1b. *In the case of the hop-mosaic these structures were undoubtedly degenerate nuclei*, for all transitions could be observed between them and the normal nuclei of the phloem. These degenerate nuclei were not observed in the phloem of healthy hop plants, but they were to be seen in the phloem of an unhealthy bean plant that had been kept some time in the poor light of a laboratory and the leaves of which were attacked by Botrytis (Fig. 1, *c*).

These results do not, of course, disprove the observations of Nelson as to the association of protozoa with virus diseases, for the diseases which he investigated have not been studied. Considering, however, how important the discovery of a causal organism in virus diseases would be, it seemed advisable to put on record the results obtained with diseased hops and beans.

Such results indicate clearly that the theory of the association of protozoa with virus diseases requires fuller evidence than has yet been supplied. It is to be noted that Nelson describes the protozoa in the plants he examined as usually existing singly in the cells, and as always elongated in the direction of the axis of the stem, *i.e.*, the organisms stand permanently on end in the plant. These somewhat remarkable results would find an easy explanation if the structures in question were no more than the degenerating nuclei of the elongated cells of the phloem.

FIG. 1.—Longitudinal sections of the phloem. *a* and *b*, a mosaic hop stem. ×1000; *c*, an unhealthy bean plant. ×600.

The Scattering of Light by Liquid and Solid Surfaces.

IT is a well-known fact of observation that most reflecting surfaces usually also scatter a little light and are thus rendered visible. The effect is usually dismissed, however, as due to dust or imperfect polish of the surface, and little attention has been given to the problem of determining whether, when these disturbing factors are eliminated, any scattering by the surface persists. Experiments carried out by the writer in collaboration with Mr. L. A. Ramdas to test this matter have led to some interesting results.

Freshly split cleavage faces of crystals show extraordinarily little scattering. In fact, it is found that a clean good piece of mica has surfaces which are invisible even when placed at the focus of a lens illuminated by sunlight against a dark background. This is what one would expect theoretically. Cleavage surfaces of rock-salt and Iceland spar are also good, though not so perfect. The conchoidal fracture-surfaces of quartz are relatively very imperfect optically. Blocks of thick plate glass when freshly broken open exhibit surfaces which apparently are quite smooth, but when illuminated by sunlight they show a blue superficial opalescence. Freshly-blown bulbs of glass when held in a strong light also show this surface opalescence very well.

Coming to liquids, the most interesting case is that of metallic mercury. After carrying out a series of chemical purifications, washing and drying the mercury and then distilling it in vacuum from one bulb to another and transferring it back again repeatedly, Mr. Ramdas succeeded in obtaining surfaces which were dust-free and chemically clean. When sunlight is concentrated on such a mercury surface in a vacuum, the focal spot shows a bluish-white opalescence, the scattered light when observed in a direction nearly parallel to the surface being very strongly polarised with the electric vector perpendicular to the surface and of nearly similar intensity in all azimuths. The opalescent spot when examined under a microscope appears perfectly structureless, showing that it is a true molecular phenomenon.

To test whether the surface-opalescence exhibited by mercury is due to the mobility of the dispersion-electrons usually assumed to exist in metals, or whether it is due to the rugosities of the surface caused by molecular bombardment, observations were also made with transparent liquids in enclosed bulbs made dust-free by repeated distillation. Various liquids tried, *e.g.* ether, alcohol, benzene, carbon tetrachloride, liquid carbon dioxide, all showed the surface-opalescence conspicuously under strong illumination. The character of the effect in these cases was, however, quite different from that shown by a clean mercury surface.

The surface-scattering by transparent liquids is undoubtedly due to the effect of molecular bombardment of the surface. It is much more intense when observed in directions adjacent to that of regular reflection and refraction than in other directions. It is less blue than the internally-scattered light, and shows remarkable changes in its state of polarisation with varying angles of incidence and observation. There were notable differences in this respect between the cases in which the light is incident respectively within and outside the liquid on the interface. There is a rapid falling off in the intensity of the surface opalescence when the angle of incidence is increased much beyond the critical angle. These facts clearly indicate that the effect shown by transparent liquids is essentially due to the imperfect planeness of the surface. The scattering by a metallic liquid surface, on the other hand, has probably a different origin, as suggested above.

The interface between two non-miscible dust-free liquids also shows strong opalescence under illumination. For the particular case in which the interfacial tension is very small or negligible, the opalescence becomes greatly exaggerated. Some observations by Mandelstamm (*Ann. d. Phys.* vol. 41, 1913) on the critical state of liquid mixtures are of interest in this connexion.

The experimental observation of the surface-opalescence of *water* presents special difficulties owing to the great ease with which this liquid catches dust and grease. The difficulties have, however, been successfully overcome and the effect satisfactorily demonstrated, both with water rendered dust-free in sealed bulbs and with the water-film on a clean block of melting ice kept free of dust by a gentle stream of gas blowing upon it.

On Continuous Radiation from the Sun.

PROF. J. Q. STEWART recently published in these columns (NATURE, February 10, p. 186) a very interesting communication on the optical and electrical properties of ionised gases. For some time past I have been engaged in investigations on similar lines, and I wish to direct attention to one important side-result. It is well known that in estimating the surface temperature of heavenly bodies (as has been done by Coblentz, Abbot, Wilsing and Scheiner, and others), from their continuous spectra, it is always tacitly assumed that they radiate like perfectly black bodies. Several investigators have pointed out that this assumption does not tally with experimental results. The temperature obtained by applying the total radiation law and the method of isochromatics to the spectral-energy curve are at variance with each other. They are also different from the temperatures obtained from the ionisation-theory.

The best example is afforded by the sun, which, according to the careful measurements of Abbot and Wilsing, shows a spectral-energy curve considerably deviating from that of a black body (see E. A. Milne, Phil. Trans. vol. 223, p. 218); the fact has been discussed by many investigators, including Schwarzschild, Groot, Milne, Dietzius, and others. There are very weighty reasons why the sun would not radiate like a black body. A black body or a full radiator is one which absorbs all the radiant energy which falls on it, reflecting none. Such an ideal body is nowhere met with in the world, but Wien and Lummer realised it by making use of a hollow enclosure maintained at a constant temperature, and provided with a small hole, the idea being that a beam of radiation within the enclosure would describe an infinitely circuitous path, and what the emission lacks in fullness will be made up by repeated reflections.

It is clear that none of these conditions is fulfilled in the case of the sun. The surface of the sun contains a large percentage of free electrons, and positive charges, which endow it with a large reflecting power. This point will be clear if we remember the analogous case of metals. According to the electromagnetic theory, metals derive their high reflecting power from the presence in them of a large number of free electrons, or rather electrons which are easily excited to vibration by incident radiation. A theory of emissivity of metals on this basis was worked out by Aschkinass in 1905, and has been verified by the experiments of Rubens and Hagen, Langmuir, and others.

The presence of a large percentage of free electrons on the surface of the sun would, thus, endow it with a high reflecting power. The surface being an open one, the hollow enclosure condition is not realised. Thus the conclusion seems to be irresistible that the total emission from the surface would fall far short of that of full radiator. The form of the spectral-energy curve suggests the emissivity E_λ varies as $\frac{A}{\lambda^{6+x}}\phi(\lambda\theta)$ where $1 > x > \frac{1}{2}$, but about this point judgment should be reserved now.

Turning to the stars, it is easy to see that similar conditions would hold. The analogy with metals enables us to say that the emission from low temperature stars would fall far short of that from a full radiator at the same temperature, while for stars with very high temperature, emissivity may approach that of a black body.

Prof. Eddington's work on the constitution of stars is based on the assumption that inside the stars total emissivity varies as T^4; this assumption is probably not affected, for, inside the stars, the hollow enclosure condition is largely fulfilled.

Separation of Common Lead into Fractions of Different Density.

BY fractional crystallisation of lead assay foil, about 300 grams in all, two end fractions, each weighing about 60 grams, were obtained. These fractions were then purified according to Stas's method. For the density determinations, about ten grams of each was melted in an atmosphere of hydrogen and allowed to solidify in a vacuum. The densities of samples prepared in this way were determined in specific gravity bottles.

Density of lead from *crystals* end of fractionating series :—$11 \cdot 345 \pm 0 \cdot 005$.

Density of lead from *mother liquor* end of fractionating series :—$11 \cdot 313 \pm 0 \cdot 005$.

A sample of Stas lead, which Mr. C. T. Heycock very kindly gave me, was found to have the density 11·328 in one experiment and 11·326 after re-melting.

The difference in density between the above-mentioned fractions persisted after granulating the metal and also after re-melting the granulated metal under potassium cyanide. It was discovered in the course of these experiments that lead which has solidified slowly is not homogeneous as regards density,—the parts which freeze first being denser.

Out of eleven experiments, only one was inconsistent with the view that the original lead had been separated into two fractions which had different densities.

The work is being continued.

Proposed International Survey of the Sky.

ON the initiative of the French National Meteorological Service, it has been decided to take photographs of the clouds three times daily during the week September 17-23, inclusive, at as many stations as possible throughout the countries of western Europe. As the number of official meteorological stations is limited, it has been proposed to enlist the services of those professional and amateur photographers who are willing to co-operate voluntarily in the work. The photographs should be taken as nearly as possible at 7 A.M., 1 P.M., and 6 P.M. G.M.T. (not summer time). The photographer should make a note of the direction in which the camera is pointing when the photograph is taken (*e.g.* north, south-west, etc.); if more than one photograph is taken at any

hour it will be advantageous to take them in opposite directions (*e.g.* south-west and north-east). A reseau of five photographs would practically cover the whole visible sky when an average lens is employed, and it is accordingly recommended that, when possible, one photograph should be taken towards each of the points north, east, south, and west, and one towards the zenith. Photographers should be particularly careful to mark their plates in some way, so that the photographs in the different directions may be readily recognised after development; the inclusion of a small strip of horizon might be advisable for this purpose. In the case of the zenith photograph, a small part of some object might be included (*e.g.* the top of a tree or the corner of the roof of a house) to indicate the orientation of the plate.

The main object is not to secure artistic effects, but rather to obtain clearly defined records of the cloud forms present, and therefore "contrasty" results are preferable.

Photographers who are willing to take part voluntarily in this work are invited to send their names to one of us at Stoner Hill, Petersfield, and these volunteers will be supplied with the necessary instructions when these are ready for distribution. At the request of Col. Delcambre, of the French Meteorological Service, instructions for taking the photographs have been drawn up by one of us and are to be circulated internationally.

C. J. P. CAVE.
G. AUBOURNE CLARKE.

An Einstein Paradox: an Apology.

ALLOW me to express regret for having misinterpreted Prof. Einstein's symbols. My mistake was caused by the fixed idea that it was impossible for K_1 *in motion* to learn anything about the signal at L *until the light reached him.*

I owe to Mr. C. O. Bartrum the explanation that there are three events, namely, (1) the emission of light-signal at L; (2) its reception by K_1; (3) its reception by K; and that each requires its own double set of space-time co-ordinates; thus (x_1, t_1), (x_2, t_2), (x_3, t_3) in K's system and the same letters with accents for K_1's. There will then be three pairs of Einstein equations.

I find, however, from letters received, that opinions differ as to the interpretation of the t's. Some think that they are the actual times recorded by the clocks; others that they have to be corrected by allowances for the passage of light. Some think that a body in motion actually contracts and that a carried clock goes slow; others that the body only seems to contract and that each of the two observers thinks that the other's clock goes slow. The latter have a difficulty in explaining the constant c.

The simple problem of which the Newtonian solution was given in NATURE of June 2 ought to admit of a solution by relativity methods. I should be greatly obliged to any of your readers who would send me one showing the time on K's clock when the signal reaches K, viz. $x_1/v + x_1/c$.

Southborough, Kent.

Colour Vision and Colour Vision Theories.

PROF. PEDDIE, in NATURE of August 4, p. 163, has dealt with some of my strictures of the trichromatic theory. Whilst nothing can be said against his mathematical presentation of the theory, it can easily be shown that, when a case of colour blindness is fully and carefully examined, the mathematical presentation will not account for the facts. All the facts which are explained by the trichromatic theory are, however, consistent with my theory.

The trichromatic theory becomes more and more complicated with subsidiary hypotheses, inconsistent with each other. I have examined a man stated to be completely red blind, but tested with my lantern he recognised red as easily as a normal-sighted person. How do 50 per cent. of the dangerously colour blind get through the wool test? The trichromatic theory completely fails to explain the trichromic class of the colour blind. The trichromic have no yellow sensation, regarding this region of the spectrum as red-green and marking out in the spectrum a monochromatic division including yellow, orange-yellow, and yellow-green.

If the trichromatic theory were true the point where the hypothetical curves cut should be shifted towards the defective sensation; this is not found. Let the trichrome now be examined by colour-mixing methods, and he may make an equation $R+G+V=W$, with too much red in the mixed light, and then make an equation with too much green in the mixed light. Again, he may agree with the normal match, or in other cases only agree with the normal match when the comparison white light is diminished in one case or increased in another, thus matching two white lights of different luminosities.

F. W. EDRIDGE-GREEN.

London, August 7.

Stirling's Theorem.

THE recent correspondence in the columns of NATURE on this subject prompts me to add to the collection a formula which I deduced about three years ago. It was then communicated to a mathematical friend, but has not otherwise been published.

The ordinary Euler-Maclaurin series for $\log_e n!$ is

$$\log\sqrt{2\pi} + (n+\tfrac{1}{2})\log n - n + 1/12n - 1/360n^3 + 1/1260n^5 \ldots$$

It is easily shown that the last three terms printed above are reproduced exactly by the first three terms of the binomial

$$\frac{1}{12n}\left(1+\frac{113}{210n^2}\right)^{-7/113};$$

while the simpler binomial

$$\frac{1}{12n}\left(1+\frac{8}{15n^2}\right)^{-1/16}, \text{ or } \frac{1}{12n}\left(\frac{15n^2}{15n^2+8}\right)^{1/16},$$

reproduces exactly the terms in $1/n$ and $1/n^3$ and very approximately the term in $1/n^5$. Adopting the simpler form, we have

$$\log n! \doteqdot \log\sqrt{2\pi} + (n+\tfrac{1}{2})\log n - n + \frac{1}{12n}\left(\frac{15n^2}{15n^2+8}\right)^{1/16},$$

or passing to common logs ($M =$ modulus),

$$\log_{10} n! \doteqdot 0{\cdot}39908993 \ldots + (n+\tfrac{1}{2})\log_{10} n - nM + \frac{M}{12n}\left(\frac{15n^2}{15n^2+8}\right)^{1/16}.$$

This formula gives for 1! (true value 1), 1·00007 . . .; for 2! (true value 2), 2·000002 . . .; for 3! and 5! no discrepancy is shown by 7-figure logs and 9-figure logs respectively. The degree of approximation is therefore high and even remarkable; but it may be doubted whether this formula or any of those under discussion is really to be preferred to the direct use of the series of which we can easily take as many terms as may be required for the order of accuracy desired.

The Growth of the Telescope.[1]

By Dr. WILLIAM J. S. LOCKYER.

IN the beginning of the year 1608, that is, 315 years ago, or about ten generations, telescopes did not exist. The main work of astronomers before the year 1608 was, therefore, concentrated upon observing and recording the positions of the heavenly bodies from day to day and from year to year. The early (1587) instruments for observations of position took the form of graduated quadrants mounted in a vertical plane capable of rotation about the centre of a horizontal divided circle. The direction of a heavenly body could be indicated only by pointing at it; so every quadrant was furnished with a pointer pivoted at the centre of the quadrant. The adjustments of the instruments were made by using a plumb line for the determination of the vertical, and a level for placing the azimuth circle horizontal.

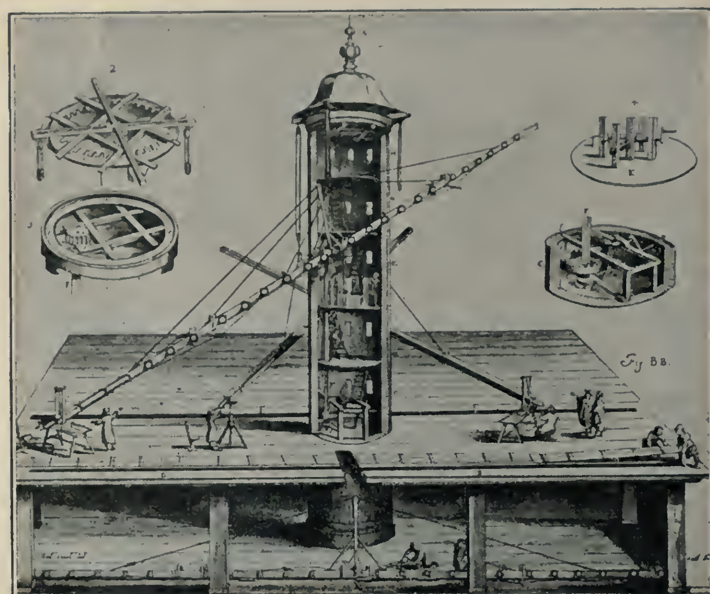

FIG. 1.—Hevelius's aerial telescopes mounted by suspension from the roof of a tower which can be rotated by gearing.

Tycho Brahe, the famous Danish astronomer (1546–1601), constructed many elaborate instruments of this nature for his observatory at Uraniberg, but his most important instrument was the large quadrant fixed in the meridian with which he observed transits of the heavenly bodies through a hole in the south wall. This instrument was the forerunner of the modern transit circle.

Galileo was the first to use the "optik tube" for the study of the heavenly bodies, and in consequence made a series of important discoveries. Thus, he found that the number of stars was enormously increased; the "wandering stars" were really planets; the moon displayed mountains; Jupiter possessed a family of satellites; Saturn exhibited curious features which were eventually identified as a ring system; Venus appeared as a crescent; spots were visible on the solar surface, etc. The lens combination employed by Galileo underwent changes as time advanced. In 1620 Kepler suggested the use of two double convex lenses, and this was actually carried out by Scheiner in 1637. Astronomers had to wait nearly 100 years before Chester More Hall, in 1733, put forward the idea of making an object-glass of two different kinds of glass—crown and flint—placed close together, thus establishing the so-called achromatic lens. It was not, however, until another quarter of a century had passed that John Dollond in 1758 rendered this discovery effective, thus heralding the dawn of what may be termed modern astronomical observation.

In the year 1639 the discovery of another form of telescope was made, namely, the reflecting telescope; but it was not until the year 1663 that the principle was described in practical form by James Gregory. It was left, however, to Sir Isaac Newton in 1668 actually to construct an instrument of this nature, and the telescope he made, which is quite small, is to-day in the rooms of the Royal Society of London. Like the refracting telescope, the reflecting telescope underwent various changes in the optical train; thus we have the forms now known as the Newtonian, Gregorian, Cassegrainian, and Herschelian.

As soon as the refracting telescope became a practical instrument it was at once brought into commission for instruments employed in the measurements of the positions of the heavenly bodies. In fact, it at once replaced "pointers." Tycho Brahe's great quadrant was soon superseded by a type of instrument similar to that made in 1770 by Sisson for the Kew Observatory. This was an 8-foot quadrant, mounted in the meridian, with a finely divided scale and vernier. The quadrant form developed later into a complete graduated circle read by several microscopes after the type of Gambey's mural circle, made in 1819 for the Paris Observatory.

The acme of perfection in accuracy is reached to-day by such an instrument as the present Cape Observatory transit circle. In this the telescope has an objective of 6 inches aperture of the finest construction, two very finely graduated circles are attached, and several micrometers are employed for reading each circle. Many other refinements, too numerous to mention here, are included to attain the highest accuracy.

In order to follow the developments of the two kinds of telescopes, namely the refractors and reflectors, it is best to deal with each kind separately. Returning to the epoch many years before John Dollond made the achromatic lens effective, it was found that an object glass, which then consisted of a single lens only, formed images at the focus which were highly coloured and spoilt definition. The only method of securing greater magnifying power, with increase of aperture or diameter of lens, was to make the lenses of great

[1] From a discourse delivered at the Royal Institution on Friday evening, April 20.

focal length; for experience had shown that the greater the focal length the less the colour.

Thus, about the year 1680 we come to the age of giant telescopes, when their lengths measured anything from 60 feet to 210 feet. These cumbrous instruments were generally suspended by their middle from tall masts or towers, and to reduce their weight diaphragms placed at stated intervals took the place of wooden tubes. Thus were the telescopes of Hevelius. Huyghens adopted the novel principle of only placing the object glass on the mast, the eyepiece being attached to it by a long cord which could be stretched tight, and so make the proper optical alignment.

An illustration of a giant observatory of Hevelius's time given here (Fig. 1) displays three of these long telescopes in use. Mechanism is shown by which not only can the telescopes be hoisted into position but the roof of the tower to which the telescopes are suspended can also be turned round to neutralise the earth's motion. The illustration shows that even in those days a considerable observatory staff was necessary.

A telescope cannot be properly manipulated unless it is equatorially mounted, *i.e.* mounted on an axis inclined to the latitude in which it is used. One of the first, if not the first, telescope to be set up in this manner was that used by Scheiner in 1618 for observing the spots on the sun. Scheiner had only to direct the telescope to the sun, and fix it in declination, when the diurnal movement could be compensated by simply moving the telescope westward by hand. The form of mounting he adopted was the foundation of the German type of mounting telescopes, to which reference will be made later.

Not only is it imperative for a telescope to be equatorially mounted, but it must also be driven by some power, clockwork or otherwise, so that the object under observation will always remain in the centre of the field of view of the telescope. Hooke, so far as is known, was the first to adopt this principle in 1674. As is indicated in an old print of his instrument, he mounted his quadrant at the upper end of a long polar axis, and rotated this by means of gear wheels actuated by a falling weight. The speed was controlled by a conical pendulum governor, which could be shortened or lengthened at will. We had to wait, however, until the year 1823 before a really efficient driving clock was applied to a telescope. This was the work of Fraunhofer, and was adapted to the 9½-in. Dorpat refractor, the largest refractor of that period, made for the Czar Nicholas of Russia. The principle is the same as that used to-day; the clockwork, driven by weights and controlled by a governor, actuating a tangent screw which is in gear with the threads cut in the circumference of the driving circle to which the telescope can be clamped. The Dorpat instrument may be said to be the first real modern refractor, as it embodied all the fundamental features of telescopes constructed afterwards.

There are three well-known recognised forms of mounting telescopes, illustrated in Fig. 2, and termed the "English," "German," and "Composite" types. In the English type the telescope tube is mounted directly on the polar axis midway between the supports of this axis, and being symmetrically placed balances itself both in Right Ascension and Declination. The composite type is rather similar to that of the English,

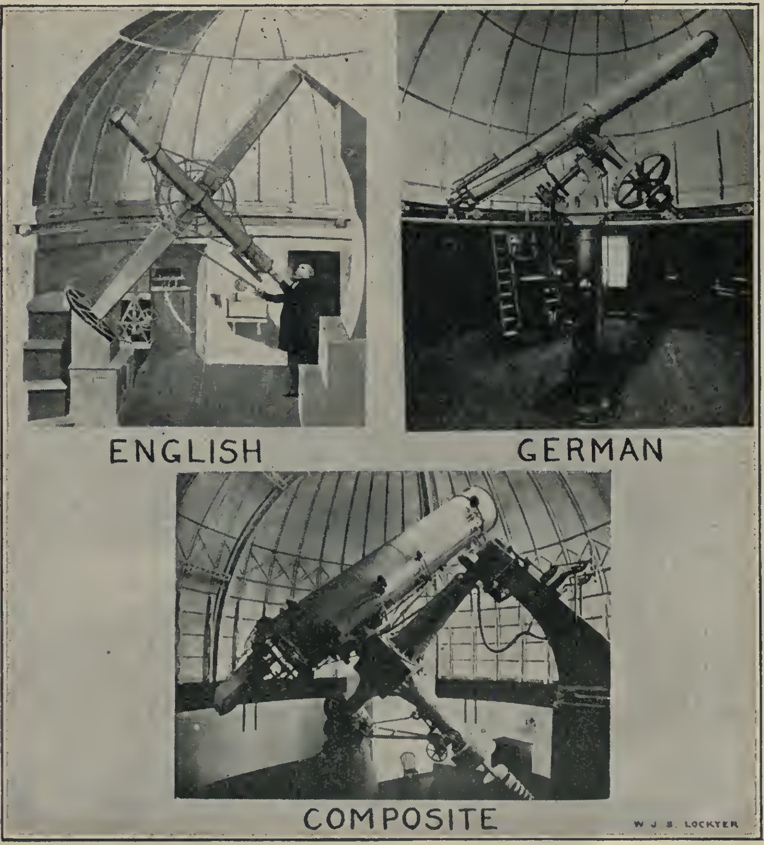

Fig. 2.—The three main methods of mounting telescopes.

only the tube is placed on one side of the polar axis and the counterpoise weights on the opposite side. In the German type, the tube with its counterpoise weights is fixed symmetrically to the prolongation of the upper end of the polar axis, that is, outside the supports of this axis. There is still a more modern modification of the German type, in which the polar axis is prolonged at its upper end, taking the shape of a fork. The telescope tube is placed symmetrically in this fork, thus obviating the necessity for counterpoise weights.

Coming now to the advance in telescope construction, mention only may be made of such instruments as the 15-inch Pulkowa (1839) by Merz and Mahler, the 15-inch Harvard (1847), also by Merz and Mahler, and the 18-inch Chicago University telescope (1862), by Alvan Clark.

The year 1868 saw the completion of the fine 25-inch

made by Cooke for Mr. R. S. Newall's observatory at Gateshead. This instrument, by far the largest of its day, was mounted after the German form. It had a focal length of 30 feet, so that the dome and observing chair had to be of great proportions. So satisfactory was the behaviour of this instrument, that, after a journey to this country to inspect this telescope, the representatives from the Washington Observatory ordered a 26-inch of 32-feet focal length from Alvan Clark, and it was completed in 1873.

In 1880, Grubb surpassed this size by making a 27-inch for the Vienna Observatory; but five years later (1885) Alvan Clark turned out a 30-inch objective of 42-feet focal length for the Pulkowa Observatory. The following year (1886) saw another objective of the same size constructed by the Brothers Henry for the Nice Observatory, but this was soon eclipsed by the completion in 1887, by Alvan Clark, of the Great Lick Refractor of 36-inch aperture and 57-feet focal length, erected on Mount Hamilton, in California. For this instrument an observing chair, as such, had to be abandoned, but the floor of the observatory was made capable of elevation and depression, thus avoiding many difficulties and adding great facilities.

Two large telescopes, though not records in size, followed the construction of the Lick instrument. The first was the 28-inch of 28 feet focal length by Grubb (1893) for the Greenwich Observatory, mounted after the English fashion; this is the largest refractor in Great Britain to-day. In the following year (1894) the Brothers Henry completed the 32-inch, 53 feet focal length telescope for the Astrophysical Observatory at Meudon, near Paris.

The largest refractor in the world to-day, namely the Yerkes telescope of the University of Chicago, was completed in 1895, the object glass by Alvan Clark being 40-inch in diameter and of 62-feet focal length. It is mounted very similarly to the Lick instrument and fitted with all the latest facilities for assisting the observer at the eye end, including a rising and falling floor.

In mounting large refractors the standard forms have occasionally been departed from in order to attain some special end. Four examples of these may be mentioned here. Thus at the Paris Observatory there was erected in 1890 a 23½-inch objective of 62-feet focal length in a tube mounted in the "Coudé" form after the design of Monsieur Loewy. This instrument is so constructed that the observer is housed in a comfortable room in which the eye end of the telescope is suitably fixed, and he can observe any object in the heavens, without moving from his chair, by means of reflections from two mirrors in the peculiar shaped tube after the light has passed through the object glass.

Another novel form was exhibited at the Paris Exhibition of 1900 to utilise an object glass of 49 inches aperture and 197 feet focal length made by Monsieur Gautier. In order to avoid the necessity of having to move such a heavy object-glass and tube, the principle adopted was to place the telescope horizontally in a true north and south position with the object-glass facing north. The light from any celestial object was then reflected into this tube by means of a large silver-on-glass mirror mounted as a siderostat and moved by clockwork. This particular telescope has never been effectively used, so in spite of its great objective it has not been classed as the greatest telescope of to-day.

A curious mounting is that employed for the 27-inch telescope of 70 feet focal length of the Treptow Observatory, near Berlin, erected in 1909. The main object in the construction was to obviate the cost of a large dome and rising floor, and also to make the eye-piece of the instrument very easy of access for numerous visitors. To accomplish this, the tube was erected on the modified German type of mounting in such a way that the eye end of the tube should be situated just above the upper end of the polar axis. The tube was counterpoised in declination by two great weights placed at the extremities of two long arms extending northwards and symmetrically placed as regards the tube. Thus the eyepiece was in the centre of motion of the telescope and practically stationary for all positions of the tube: also by simply setting the tube near the position of horizontality it could be covered by a light wooden low structure.

The last novel form of mounting to be mentioned was erected in 1912, and is known as the 150-foot Tower Telescope of the Mount Wilson Observatory. Its origin developed from the fact that an objective of long focal length was required to be used in conjunction with a spectroscope also of long focal length.

Previous experience had shown that air currents near the ground affected the definition when such long instruments were used in a horizontal position. Dr. G. E. Hale conceived the idea of mounting the object lens high up on a metal girder tower and throwing the images of the celestial object to be studied vertically downwards on to the spectroscope placed vertically in a shaft in the ground, employing two plane mirrors above the object-glass to reflect the object downwards. The actual lens in use has an aperture of 12 inches and a focal length of 150 feet, while the focal length of the spectroscope is 75 feet. One of the chief peculiarities of the construction was that the girder work of the Tower was really in duplicate, one within the other and not touching at any place. While the dome at the top rested on the outer casing, the mirrors and lens were supported by the inner one; thus any wind pressure which might set up vibration in the outer casing did not affect the inner casing which supported the optical parts of the arrangement.

Reference has previously been made to the various forms of reflecting telescopes, such as the Newtonian, Gregorian, Cassegrainian, and Herschelian, and to the first reflector ever made, namely, that by Sir Isaac Newton in 1668. For a long time the progress of this type of telescope was slow, but impetus was given to it by Sir William Herschel, who was the first to make mirrors of really large dimensions. The mirrors themselves were composed of speculum metal—an alloy of copper and tin and highly polished. Herschel's largest reflector was four feet in diameter, with a focal length of forty feet. It was erected at Slough, near Windsor, in the year 1789. The tube was pivoted near the ground and mounted between high wooden trestles: while there was no restriction to its movement in the vertical direction it was only capable of a very small lateral motion east and west of the meridian. Just as Galileo, with his pigmy refractor, revolutionised ideas with his wonderful discoveries, so Herschel with the

giant reflector of his own construction made momentous additions to our astronomical knowledge.

Nearly sixty years later (1845) Lord Rosse ground, polished, and mounted a six-foot reflector at Parsonstown in Ireland. This leviathan of 54 feet focal length was mounted somewhat after the fashion of Herschel's, but solid masonry replaced the wooden-trestle structure. The movements of the tube were also similarly restricted.

While Lassel's reflectors, the largest of which was four foot and made in 1863, were not an advance in size, yet he instituted a great improvement by mounting the instrument equatorially after the modified German type. Grubb in 1870 completed a mirror of the same dimensions for the Melbourne Observatory, mounting it in the composite fashion. This was the last large reflector which employed a mirror of speculum metal, because glass mirrors were beginning to supersede them.

In the years 1856 and 1857 Steinheil and Foucault discovered a method of making mirrors by depositing silver on glass surfaces. This produced a highly efficient reflecting surface and soon came into common use. One of the first large reflectors with this type of mirror was that made by Foucault himself for the Paris Observatory. It was constructed on the Newtonian principle, mounted equatorially on a heavy wooden framework movable on castors and clock driven. In 1875 Martin made a four-foot mirror for the same observatory, and it was only owing to the thinness of the glass disc in relation to its diameter that it was not a success. The completed instrument was mounted in the composite form.

An immense advance was made by Common, who in 1888 constructed and used a mirror of five feet diameter. The tube was mounted on the modified German plan, being placed in a fork bolted to the upper end of the polar axis. To minimise the great weight of the polar axis on its bearings the novel idea of floating it was adopted. It was not till the year 1908, that is, twenty years later, that a mirror of the same size was made. This was accomplished by Ritchey for the Mount Wilson Observatory: the style of mounting was rather similar to that adopted by Common.

Another ten years saw the completion (1918) of the six-foot reflector for the Dominion Observatory, Ottawa. This great glass, the work of Brashear, is equal in size to the speculum mirror of Lord Rosse and weighs two tons. The form of mounting of the tube is after the composite type, the moving parts weighing 35 tons. The telescope is capable of being used either as a Newtonian or as a Cassegrainian.

It should be noted that "rising floors" in an observatory cannot be employed for reflecting telescopes of the Newtonian form because the eye end of the telescope is situated at the upper end of the tube. The staging to accommodate the observer is therefore of very complex construction, and the arrangements adopted vary very considerably from one instrument to another, no two forms being alike.

We come now to the largest reflector of the present time, namely the Hooker 100-inch erected at the Mount Wilson Observatory in 1919. This mirror of 13 inches thickness, and weighing four and one-half tons, has a focal length of 42 feet. Though the block of glass was cast in France, the figuring and silvering is due to the skill of Ritchey. The great tube carrying the mirror is mounted after the English type, and the moving parts of the telescope amount in all to fourteen and one-half tons. Either the Newtonian or Cassegrainian form of instrument can be utilised. Thus, after a lapse of two and a half centuries, the one-inch reflecting telescope of Sir Isaac Newton has grown into a monster of 100 inches.

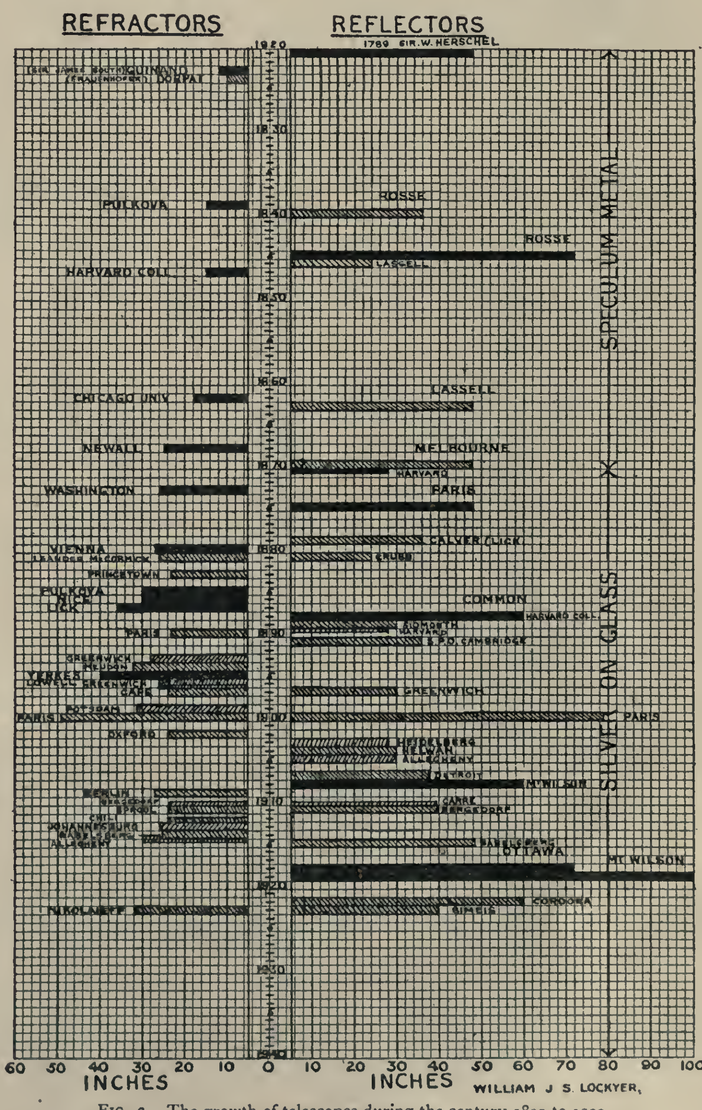

FIG. 3.—The growth of telescopes during the century 1820 to 1920.

Having thus separately surveyed the progress of the two types of telescopes, it is interesting to obtain a bird's-eye view of this growth. This is represented by

means of the accompanying diagram (Fig. 3). The period of time covered is the century beginning in 1820, and while the years are displayed down the centre of the diagram, the size (in inches) of the object glasses and mirrors are shown respectively on the left- and right-hand sides against the years of their erection. Many other large instruments of interest, apart from those that were records in size in their time, have been inserted.

No less interesting and important is the study of the geographical distribution of large telescopes. For this purpose the positions of the great telescopes have been indicated on a chart of the world (Fig. 4). On this diagram refractors from 30 to 40 inches aperture are represented by large black spots, and those between 20 and 29 inches by small black dots. On the other hand, reflectors from 60 to 100 inches in diameter are indicated by large circles, and those from 30 to 59 inches by small circles. It will be seen that the very large telescopes predominate in two main regions, namely Europe and the United States of America with Canada. Only one telescope of the very large type is situated in the southern hemisphere, and that is the five-foot reflector for the Argentine National Observatory at Cordoba. This instrument, although completed, has not yet been erected.

South Africa and Australia are both blank in this respect, except that a 26-inch refractor is nearing completion for the former, but it is hoped that in the near future both these countries will be better represented.

The limit of size of a telescope, whether it be refractor or reflector, for the accomplishment of useful work has by no means yet been reached, providing the instrument be placed in a specially selected locality high up on some extensive plateau, where the "seeing" is of a high-class nature during the greater part of the year.

This limit is at present only temporarily restricted by the maximum limit that can be reached by those whose work it is to cast the necessary glass blocks. The mounting of even the largest telescope is now only a mild engineering problem.

It must not be forgotten, however, that large telescopes are very expensive not only to construct but also to house; yet experience has shown, at any rate in the United States of America, that when occasion arises an enthusiastic private donor generally appears.

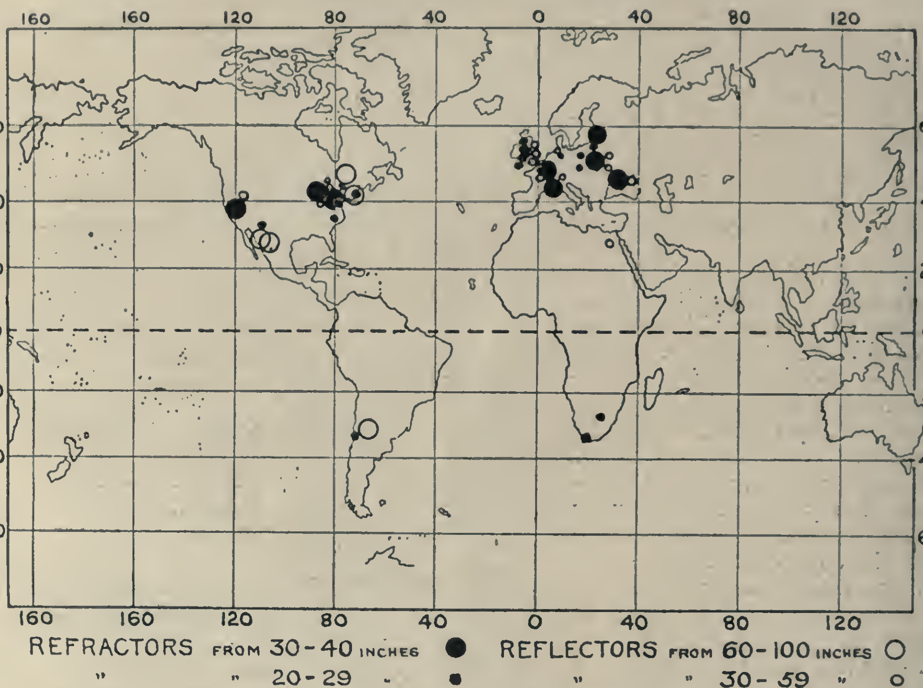

FIG. 4.—Geographical distribution of large telescopes.

Obituary.

THE death is announced of Dr. Hermann Biggs, Commissioner of Health, New York State, at the age of sixty-three. After graduating at Bellevue Medical College, Dr. Biggs studied in Berlin and Greifswald, and returning to the United States in 1895, directed the production of the first diphtheria antitoxin in that country. In 1900 he became general medical officer of the New York City health department, and there established the first municipal bacteriological laboratory. This post he held until 1914, when he was appointed Commissioner of Health to New York State. Under his administration the health of New York City and State changed markedly for the better. He organised a campaign against tuberculosis, and was responsible for a body of wise health legislation. He was a scientific director of the Rockefeller Institute, and, for a short time, medical director of the League of Red Cross Societies. He gave to his country and to the world distinguished services, and preventive medicine loses by his death an ardent disciple. R. T. H.

Current Topics and Events.

Atomic projectiles have been used by many investigators to batter down the defences which have guarded so well the innermost mysteries of the structure of matter. The α-particle, liberated spontaneously in radioactive transformations, has, thanks to its enormous velocity, been of special service in elucidating the constitution of the atom. In these investigations no one has played a more important part than Sir Ernest Rutherford, and it is, therefore, appropriate that in the address which appears as a supplement to this issue of Nature he should give an account of the life history of such a high-speed α-particle. When the particle is expelled from a radioactive substance, it has been proved to be the nucleus of a helium atom of mass 4 carrying two positive charges of electricity. Recent experiments by Henderson have shown how, by the successive capture of electrons, the α-particle becomes a neutral helium atom. The experiments, which were carried out by observing the deflexion of a narrow pencil of α-rays in a magnetic field, have been confirmed and extended by Sir Ernest Rutherford. It appears that not only may the doubly charged helium nucleus remove and capture an electron from the outer electron structure of the atoms in its path, but the converse change may also take place. In passing through other atoms this electron may be knocked off, and the singly charged α-particle revert back to the doubly charged type. The somewhat unexpected conclusion is reached that this process of capture and loss may repeat itself more than a thousand times in the flight of the particle. Similar considerations apply in the case of singly charged and neutral helium particles. Though the results of these encounters may be less startling than those in which disintegration of an atomic nucleus like that of nitrogen or of aluminium occurs, it seems probable that the study of these rapid interchanges of charge will yield information of great value to the theoretical physicist.

The attempt to restrict the spread of epidemic disease amongst plants is creating a phytopathological service of inspection in many countries, and legislation is gradually restricting the free movements of plants and plant produce in and out of the various countries. In a paper under the title "The Biological Basis of Plant Quarantines" contributed to *Phytopathology* for June, W. A. Orton and R. Kent Beattie attempt to get down to the first principles underlying such legislation, and their views deserve careful study in Great Britain, both by growers and students of pathology, as, if the conclusions arrived at find favour in the United States, the British exporter of plants may experience increasing difficulties in the way of export trade with that country. The authors draw a fundamental distinction between communications between countries that are close neighbours, and traffic in plants across the ocean barriers that separate continents. They conclude that within the area of a continent the cultivated host plants and their parasites will in most cases have fought out their battle and arrived at an approximate equilibrium, the issue of the conflict varying of course each season, but without violent fluctuation. When, however, a parasite crosses an ocean barrier, then its arrival in the new continent may be followed by incalculable results, and a cultivated crop may almost be exterminated before selection of more resistant forms, or other factors operating over a space of time, have again produced an equilibrium in which the cultivation of the crop is economically possible, allowing for the average loss produced by this parasite. These results may follow, even when the parasite thus introduced is one regarded as relatively innocuous in the continent where it has long been known. For example, chestnut bark disease, *Endothia parasitica*, though a relatively minor trouble in Asia, has, since its introduction to America, bid fair to destroy all the chestnut forests of the country. The author's arguments bring them into disagreement with the conclusion of the last International Phytopathological Convention, held in Rome in 1914, as they emphasise the importance of "common species of long-standing dispersion" which inspecting officials naturally tend to overlook, and lead them to the very important general principle that "inter-continental trade in plant propagating material is fundamentally dangerous, and to be held within the narrowest limits compatible with economic need."

One of the best-known German scientific workers, and at the same time one of the founders of modern physical chemistry, Wilhelm Ostwald, who was born September 2, 1853, at Riga, is about to celebrate his seventieth birthday. After having studied at Dorpat he was appointed, in 1883, professor of chemistry at the Baltic Polytechnical School of Riga, and, in 1887, professor of physical chemistry in Leipzig. Here he developed a great ability as an investigator as well as a teacher. His work gave a firm experimental foundation to the theories of van 't Hoff and Sv. Arrhenius. There, scientific workers from all over the world assembled round the master, and built up, in a short time, the edifice of modern physical chemistry. Besides this work, Ostwald produced a number of valuable text-books, including his large "Outlines of General Chemistry," "The Fundamental Principles of Chemistry," "The Principles of Inorganic Chemistry," and "Scientific Foundations of Analytical Chemistry." At the end of last century Ostwald devoted himself more to questions of natural philosophy, such as the energy resources of the world. These studies, the fight against scientific materialism, and the propagation of Haeckel's monistic philosophy so occupied his mind that he gave up his professorial duties in 1906 and retired to his country seat in Grossbothen, Saxony. It was a token of the breadth and productivity of Ostwald's mind that even then he created for himself quite a new sphere of activity. Starting from the art of painting, which he had loved and cultivated since his youth, he worked out a new system of colour, by which every tint can be

characterised by exact figures. He has expounded the system in various works on colours, and it has already led to the foundation of an institute for colour investigation in Dresden. The numerous pupils and friends of Ostwald rejoice in the work of their leader and offer him their tribute of esteem.

THE second triennial Pan-Pacific Science Congress, which opened at Melbourne on August 13, is being held under the auspices of the Australian National Research Council and with the support of the Commonwealth and State Governments. The first congress was held in Honolulu in 1920, and the third will be held in some other country bordering on the Pacific. The object of these congresses is the promotion of the study of scientific problems of common interest, and the meetings form part of a general plan aiming at the maintenance of harmonious relations between all the countries within and bordering the Pacific region. In addition, therefore, to representatives from Great Britain and various parts of the Empire, distinguished men of science from the United States, Japan, and Formosa, the Netherlands, Dutch East Indies, and other countries are attending the Melbourne congress. Among the subjects under discussion are: irrigation problems; agricultural education and research; genetics, with special reference to the improvement of farm animals; organisation of research among the natives of the islands of the Pacific. (A strong effort will be made to obtain from ethnologists agreement as to a definite and practical scheme for the investigation at once of the fast-disappearing races in those islands in which Australia is especially interested. If such a scheme can be devised it will be laid before the Commonwealth Government with an urgent plea that it be put into effect at once); introduced pests and natural enemies; paper pulp: Australian possibilities; meteorology of the Pacific; terrestrial magnetism in Pacific regions; value of hydrographical work of the Royal Navy, and Australia's responsibility to continue it; survey of the Great Barrier Reef; international notification of animal diseases; hygiene of Pacific Region; fisheries and marine biological stations; parasitological problems, etc. We hope to give an account of the proceedings of the congress in a future issue.

A SPECIAL number of the *Revue Scientifique* was published on July 28, under the title of "L'Œuvre de Pasteur et ses conséquences." We may regard it as the complement of the special Pasteur number of NATURE: but it goes further afield. It contains many articles by writers of great authority: and it represents the devotion of all France to Pasteur's memory. He lived and worked for France, and wore out his life for her. His work was for the good of the world. Still, it was for the honour and glory of France: that was his revenge, after 1870, to set France high above Germany in a vast domain of science. Every year we in Great Britain, though we are grateful to him, are living under this disgrace, that we have no monument or memorial to him, to show our sense of gratitude for all that we have learned from him. Among the articles in this number of the *Revue Scientifique* are two of remarkable interest. One is on the predestined course of his discoveries, "L'Enchaînement des découvertes de Pasteur." There is no end to the wonder of this orderly and inevitable enchainment of discoveries. The other article is "Pasteur et la Maternité." It tells the story of Semmelweis and his defeat: and the story of Tarnier's work, who in one year saw, in the Maternité de Paris, 132 women, out of 2237, die of puerperal fever: indeed, in May, out of 31 admitted for confinement, 30 went out dead. Then, the wearisome debating and theorising, up to that day in 1879, March 11, in the Académie de Médecine, when Hervieux poked fun at the notion that puerperal fever was caused by germs, and Pasteur went up to the blackboard and sketched *streptococcus* on it, saying, "Tenez, voici sa figure." We see, by an advertisement in the *Revue Scientifique*, that copies of Aronson's bust of Pasteur can be had at prices according to size. Surely, some English shops ought to stock this bust. But where is our proper memorial of Pasteur in London?

A SEVERE typhoon was experienced at Hong-kong on Saturday, August 18, and much damage occurred, accompanied with loss of life. The wind is said to have attained a velocity of 130 miles an hour, which is stated to be the highest on record, and the barometer fell to 28·66 in., said to be the lowest reading on record at Hong-kong. In two hours, from 9 to 11 A.M., during the height of the storm the rainfall amounted to about 5 inches. Good notice was given of the approach of the typhoon, which was first reported on August 11, from Guahan, Ladrone Islands, in the North Pacific. The progress of the typhoon was about 270 miles a day to the west-north-west. Later reports fortunately state that Hong-kong has suffered far less than might have been expected, but the typhoon warning was again hoisted on August 20. Typhoons are regularly warned at Hong-kong by those in charge at the Royal Observatory.

IN the *General Electric Review* of America for August there is a complete technical description of the latest broadcasting station in New York. It is termed "Broadcast Central" and operates under the call letters WJY and WJZ. It was opened on May 15 and can be heard by radio listeners on the eastern side of the United States. It has "two channel" operation, so that it transmits two different programmes simultaneously. WJY, called the "jazz" channel, operates on a wave-length of 405 metres and broadcasts popular music, news, lectures, etc. The WJZ channel operates on a wave-length of 455 metres and broadcasts operatic and classical music. Both the studios are on the sixth floor of the Æolian Hall, which is in the centre of New York City. As concerts and recitals are always being given in this hall, arrangements have been made to broadcast them. Special line wires also have been run to the more important theatres and hotels, so that outside performances can be readily transmitted. The antennæ are strung from two 120-foot towers located on the roof at a distance of 175 feet apart and form two

separate four wire horizontal systems separated by ropes and insulators. The length of the wires forming one system is 45 feet, and the length of the other system is 55 feet. As the output of a high-quality microphone seldom exceeds a few millivolts, considerable amplification is necessary. A three-unit motor generator set is used. One of the generators has a 1000-volt commutator at each end, thus giving 1000 volts for the amplifier plate filter and 2000 volts for the transmitter. The equipment is all duplicated, one set being in reserve, so as to reduce the risk of a breakdown to a minimum. From the listener's point of view, this alternative choice of programmes is an attraction, and the operation of Broadcast Central has been extremely successful.

THE *New Phytologist* (vol. 22, No. 3) contains a very stimulating article by Dr. F. E. Clements under the title of "The Ecological Method in Teaching Botany," in which the author's ecological outlook is applied to the problems of teaching with the insistence upon quantitative study of environment, and the response thereto, that has proved so fruitful in his studies of vegetation. This paper should do good if only for its challenge to the traditional methods which hold such unquestioned sway, though many teachers will feel Dr. Clements's ideals—that the student's education should be based mainly upon first-hand investigation, brought into an ordered and correlated form by the method of group discussion, all the work being done "where the plants are, whether this be the greenhouse, garden, field or (much less satisfactory) the ordinary laboratory"—make demands which the staffing and accommodation of most British departments of botany would render impossible. Dr. Clements's distrust of the efficacy of lectures, his challenge to the professors' insistence upon principles as apart from facts, his criticism that the laboratory notebook, save for its indifferent quality, is more suitable to a drawing class, and his objection to the content of the typical elementary class in which morphology is paramount, are points in his paper which might well provoke animated discussion; but there can be little question that a new generation will do well to take a critical survey of the methods and results of the formal lecture and laboratory courses of their predecessors.

APPLICATIONS are invited by the Admiralty for a Junior Scientific Assistant in the Experimental department of the Signal School, the duties being concerned with the application of W/T devices; also for a Junior Scientific Assistant having a good knowledge of general physics, possessing an honours degree in physics or its equivalent, and with some experience in research. Applications for the posts should be sent to the Secretary of the Admiralty (C.E.), Admiralty, S.W.1.

REFERRING to the letter of Dr. G. D. Hale Carpenter on a waterspout with a sheath or sleeve, published in NATURE of September 23, 1922, p. 414, and one on the same subject by Dr. Willard J. Fisher in the issue of November 18, p. 669, Dr. Fisher writes to say that the same sort of sleeved tornado pendant seems to be described by R. Abercromby, in the Quart. Jour. Roy. Met. Soc., 16, pp. 119-126, 1890, as having been observed by Mr. S. Elson, a Calcutta pilot. Possibly the phenomenon is not very uncommon.

THE British Research Association for the Woollen and Worsted Industries announces the following awards for the year 1923–24: Research Fellowships: Mr. Robert Burgess, of Nottingham, to carry out investigations on the damage and deterioration caused by bacteria and fungi on woollen goods and yarns during storage; and Mr. H. E. Farrar, of Leeds, to conduct research on the dyeing of wool with acid and mordant colours. Advanced Scholarships: Mr. S. Menzer, tenable at the University of Leeds; Mr. T. N. T. Graham, tenable at the Scottish Woollen Technical College, Galashiels; Mr. P. M. Redman, of Keighley, and Mr. W. Lee, of Halifax, tenable at the Bradford Technical College.

WE have received from British Drug Houses, Ltd. (16-30 Graham Street, N.1), a specimen of their standard lactose B.D.H., which has been prepared of guaranteed purity for the particular requirements of bacteriologists and biologists. We have tested it with several strains of *Bacillus typhosus*, *B. paratyphosus*, *B. dysenteriæ*, and other micro-organisms, and find that it gives the characteristic and typical fermentation reactions of the respective organisms. One gram incinerated on platinum gave no weighable amount of ash. We therefore believe that the claim made as to the purity of this lactose is substantiated. It is supplied in 1 lb. sealed tins, price 3*s*. 6*d*. each.

THE Nouvelle Société Helvétique, 28 Red Lion Square, London, W.C.1, has just issued a useful bibliography of books dealing with Switzerland which have appeared in English since 1880. The list includes not only guide-books and tourist literature but also those on historical, constitutional, and social subjects, and in addition works by Swiss writers translated into English, as well as books in English on such pioneers as Rousseau and Pestalozzi in education and de Saussure in science. All lovers of Switzerland and its people will find the bibliography helpful and interesting. Copies may be obtained upon application to Dr. Paul Lang, Secretary of the Society, at the above address.

THE names of the green pheasant, the copper pheasant, and the golden pheasant were added to the Schedule to the Importation of Plumage (Prohibition) Act, 1921, by virtue of the Importation of Plumage (No. 2) Order, 1922, dated June 12, 1922. As was announced in the Press at the time, the Advisory Committee appointed under the Act, in recommending the addition of the names of these birds to the Schedule, further recommended that the matter should be referred to them again for review after the expiration of twelve months. The Committee has now reconsidered this question and has recommended that the golden pheasant should be included in the Schedule for a further period of twelve months, but that the copper and green pheasants should be removed from the Schedule at the end of the present year.

The Board of Trade accordingly desires it to be known that an order will be made in due course, removing the names of the copper and green pheasants from the Schedule, with effect from January 1, 1924.

Science announces that the committee of the Daniel Giraud Elliot Medal desires to receive nominations for the awards of the years 1921 and 1922, which are still open, because the committee has not been able to reach unanimous conclusion on any work thus far brought to its attention. The Elliot Medal is awarded for some especially great contribution, not for general accomplishment, in the field of either zoology or palæontology. It is not restricted in either branch to the vertebrates, but may be made in either the vertebrate or invertebrate field and is open to scientific workers of the world. The award of the gold medal is accompanied by a generous honorarium. Nominations for the two years mentioned, namely, 1921 and 1922, and also for 1923, can now be received. Communications should be addressed to the Secretary of the National Academy of Snccices, Washington, D.C.

THE eleventh meeting of the Indian Science Congress will be held at Bangalore on January 14-19, 1924. H.H. the Maharajah of Mysore will be patron of the meeting, and Sir Asutosh Mookerjee will be president. The following sectional presidents have been appointed :—Mr. B. C. Burt (agriculture) ; Prof. C. V. Raman (physics and mathematics) ; Dr. E. R. Watson (chemistry) ; Prof. K. N. Bahl (zoology) ; Prof. Agharkar (botany) ; Mr. H. Bosworth Smith (geology) ; Lieut.-Col. Christophers (medical research) ; Mr. J. Hornell (anthropology). The honorary local secretaries will be Prof. F. L. Usher, Central College, Bangalore, and Mr. S. G. Sastry, Secretary, Board of Scientific Advice, Bangalore. Further information can be obtained on application to the hon. general secretary, Dr. J. L. Simonsen, Forest Research Institute and College, Dehra Dun, U.P. India.

THE Journal of the Röntgen Society (the oldest radiological society in the world) for July (vol. xix. No. 76) contains an account of the twenty-fifth anniversary dinner of the Society held in March last, and a translation of Röntgen's first and second memoirs on X-rays, entitled "Concerning a New Kind of Ray," which are interesting reading.

THE latest catalogue (No. 378) of Messrs. Bernard Quaritch, Ltd., 11 Grafton Street, W.1, is of a miscellaneous character, but of the 1399 second-hand works offered for sale many deal with science, and, as is usual with the lists issued by this firm, some are very scarce and choice. The catalogue also comprises a list of selected new and recent publications.

THE McGraw-Hill Publishing Co., Ltd., announces an interesting new series of books under the title of "Concise Studies in Economic Problems," which will embody the results of research studies made by the Institute of Economics of Washington, D.C., U.S.A. The first volume will be "Germany's Capacity to Pay." Succeeding works will deal with International Economic Reconstruction, International Commercial Policies, Industry and Labour, and Agricultural Economics.

Our Astronomical Column.

THE DENSITY OF THE CORONA.—The question of the density of the corona is of interest both with regard to possible refraction of starlight in the investigation of the Einstein light-deviation, and with regard to the amount of resistance met with by comets of small perihelion distance. *Astr. Nach.*, 5238, contains a discussion of the subject by B. Fessenkoff, of Moscow.

The author assumes that the total light of the corona is equal to that of the full moon, and that the light intensity varies (1) as the inverse square, (2) as the inverse fourth power, of the distance from the sun's surface. He utilises some studies of his own on the light-reflecting powers of the terrestrial atmosphere at various heights, obtained from measures of the brightness of twilight for different angles of depression of the sun. He calculates that the light given by a small volume of the corona, 5′ from the sun's limb, in terms of the light given by an equal volume of terrestrial atmosphere, of the density and composition that exist at a height of 100 km., placed in the same situation as the coronal volume, is :—on supposition (1) $0{\cdot}52 \times 10^{-3}$; on supposition (2) $0{\cdot}27 \times 10^{-4}$. The density of the corona at 5′ from the limb is that of hydrogen at pressures $0{\cdot}43 \times 10^{-5}$ mm. and $0{\cdot}22 \times 10^{-6}$ mm. (temperature 0° C.) on the two suppositions. It will be remembered that the nearest stars that have been observed in the Einstein investigation were considerably further from the limb.

REPORT ON THE KAPTEYN SELECTED AREAS.—Prof. Van Rhijn, of Groningen, has issued a useful report on the progress of researches on these areas. They are distributed on a uniform plan over the celestial sphere, and are to be studied in an exhaustive manner by a number of co-operating observatories. The first step is the formation of a photographic Durchmusterung of the stars in the areas ; this is being done at Harvard and Arequipa, with apertures of 16 and 24 inches, and limiting magnitudes 15·9 and 16·3 respectively ; these plates are being measured at Groningen. It is estimated that the number of stars is about a quarter of a million, the total area being 225 square degrees, or 1/183 of the sphere. The positions are determined to an accuracy of half a second, the magnitudes to 0·1 mag. The centennial proper motions of the stars of mag. 12 and brighter are determinable to a third of a second with the aid of the *Carte de Ciel* plates ; those of the fainter stars will not be obtainable for some years with the necessary accuracy.

The best methods of determining absolute motions and eliminating magnitude error are discussed ; the author hopes that Kapteyn's plan for a photographic parallax Durchmusterung will not be abandoned. He admits that the results are illusory for particular stars, but he thinks that they will serve to compare the parallaxes of stars of the same magnitude with large and small proper motions. The colour-indices are being determined by Seares by comparison of photographs on ordinary and orthochromatic plates. Altogether the report gives a hopeful summary of the results already attained and those to be looked for in the near future.

Research Items.

TESTS OF NATURAL AND CULTURE PEARLS.—A simple optical method of distinguishing the Japanese "culture" pearls from wholly natural pearls is described by Dr. F. E. Wright in Journ. Washington Acad. Sci., 1923, vol. 13, p. 282. In a bead of mother-of-pearl, such as is always used for the nucleus of the "culture" pearls, the nacreous layers are not concentric to the surface, but are approximately plane, being parallel to the surface of the shell from which the bead was cut. Now normal to this surface the reflecting power, and consequently also the opacity, is at a maximum; whilst at 90° from this direction (that is, looking along the laminæ) there is a minimum of reflection and of opacity. A "culture" pearl when viewed in a strong reflected light (for example, with the observer's back to the sun) shows at the opposite poles of one diameter a small bright spot due to the light reflected from the laminæ of the enclosed bead of mother-of-pearl. In a strong beam of transmitted light (arranged in a closed box with lens and mirror, the pearl resting in a circular aperture) the "culture" pearl shows two positions of maximum opacity, whilst the natural pearl is the same in all positions. A third method, which is applicable also to "culture" pearls containing a real pearl as nucleus, is given by an examination of the walls of the hole drilled through the pearl. The pearl is illuminated by a strong side light and a minute bead melted on the end of a gold wire is inserted in the bore to act as a reflector, which is viewed under the microscope.

CONDENSED MILK.—An important report by Dr. Savage and Mr. Hunwicke on the manufacture, condition, bacteriology, and spoiling of commercial sweetened and unsweetened condensed milk has been issued by the Food Investigation Board (Special Rep. No. 13). The changes in the condition of the milk as a result of its concentration are profound, and not merely those caused by deprivation of water. It is, for example, a much worse conductor of heat than unconcentrated milk. While sporing aerobic bacilli are present in a considerable proportion of samples, decomposition and spoiling are nearly always due to non-sporing bacteria, particularly certain micrococci, which either survive the preliminary pasteurisation of the raw milk in the course of manufacture, or after canning are admitted to the tins through minute leaks. The sources of bacterial contamination and multiplication are mainly from the original milk, from the air of the factory, and particularly from dirty pipes and apparatus. As regards the viability of the micrococci which cause spoiling, in unsweetened condensed milk they may survive a temperature of 70° C., but are destroyed at 80° C. in a short time: this suggests that a longer pasteurisation of the raw milk might be an advantage. The best manufacturers appear to have achieved striking success, however, in dealing with such an unstable substance as milk.

RESEARCHES ON MARINE ANIMALS.—We note with pleasure that Prof. M'Intosh—the veteran naturalist—continues to publish his notes from the Gatty Marine Laboratory, the forty-fifth paper of this series appearing in the July number of the *Annals and Magazine of Natural History*. A note on variation in the wild rabbit is included, but the other items refer to marine animals. The results of a comparative study of the British species of Lepadogaster (Sucker-fishes) are set forth, the characters of the young as well as of the adults being contrasted. The sub-fossil skull of a whale found at Airthrey, near Stirling, is described and figured, and Sir William Turner's conclusion that it pertains to Sibbald's Rorqual is corroborated. A fragmentary skull of *Balæna australis*, from the Campbell Islands, is also described. Finally the variation of *Amphinome rostrata*, a Polychæte worm, is considered, and the conclusion is arrived at that the differences said to exist between specimens from the Atlantic and Indian Oceans are not specific, but are largely due to different methods of preservation. Formalin is condemned as an unsuitable preservative for animals of this group.

VIRUS DISEASES OF POTATOES.—A valuable addition to knowledge of the virus diseases of the potato (Leaf Roll, Mosaic, etc.) has been made by P. A. Murphy, of Dublin, who publishes an account of his work in the current issue of the *Journal of the Irish Department of Agriculture*. It is now well established that what has hitherto been called degeneration of the potato is not due so much to environmental causes as to the presence of infective diseases of which the perplexing feature is that no visible causative organisms have yet been discovered. The menace of these virus diseases to the economic plants of the world seems to be increasing. Already the maize and sugar-cane crops in America have been attacked over large areas of the country. In addition to the potato these diseases (it may be the same disease) in the British Isles attack the tomato, mangel, and the hop. It was shown some years ago by Quanjer in Holland that the infection is transmitted from plant to plant by species of aphis. Mr. Murphy has now proved that other insects infesting the potato, such as various species of Jassid and Capsid, are capable of transmitting infection. In this connexion it is interesting to learn that potatoes when grown in the North of Scotland are not so liable to infection, and it has been suggested that this is due to the absence of disease-carrying insects at a sufficiently early stage of the growth of the plant. Whatever the reason may be, it is undoubted that tubers imported into the south from this region are generally free from disease and produce a much heavier crop of potatoes than that raised from indigenous "seed." Mr. Murphy also shows that certain varieties of potatoes are less liable to infection than others. One of his most interesting experiments was an attempt to secure healthy tubers for "seed" by "rogueing" out obviously infected plants. The result was unfortunately inconclusive, and it appears doubtful whether immunity from attack can be secured by this means. Another perplexing feature of these diseases probably stands in the way. There appears to be no doubt that certain plants (including Solanaceous weeds) act as carriers of the disease, and may therefore be the means of infecting other plants, while showing no visible signs of infection themselves.

TERMITES OF BARKUDA ISLAND.—In a recent part of the Records of the Indian Museum (vol. xxv. part II.) is a memoir on the Termites of Barkuda Island in the Chilka Lake. The systematic characters of the genera and species are described by Prof. F. Silvestri, the habits by Dr. N. Annandale, and the fungi cultivated by the termites by Prof. S. R. Bose. Dr. Annandale divides these termites biologically into three categories—burrowers, mound-builders, and log-dwellers—a classification which, as he points out, does not correspond with the taxonomic one. He discusses the swarming, the duration of life, the cultivation of fungi and the search for food, and the details of structure of the nests.

PARASITIC NEMATODES.—Dr. H. A. Baylis and Mr. R. Daubeny (*Memoirs Indian Mus.*, vii. pp. 263-347) report on the parasitic nematodes in the collection of the Zoological Survey of India. The material, which includes about eighty species, was collected

from animals, mostly Indian, in the Zoological Garden, Calcutta. One of the most interesting records is that of full-sized specimens of *Ascaris lumbricoides* in squirrels. The authors have compared these specimens with others from man and from an Indian wild pig—paying particular attention to the characters of the lips, of the posterior end of the male, and of the eggs—and they conclude that all belong to the same species. *Ancylostoma duodenale* is recorded from the tiger, the specimens being somewhat smaller than those from man, as has been noted in regard to examples previously found in the tiger. *Necator americanus* was found in a new host, namely, a young African rhinoceros which was captured in Tanganyika Territory and had lived in the Calcutta Zoological Garden only a very short time. Two larvæ taken from a prawn are tentatively referred to the genus Eustrongylides, and are apparently the first examples of the genus to be recorded from an invertebrate.

FOSSIL BARNACLES OF INDIA.—The receipt of fresh material at the Natural History Museum has led Mr. T. H. Withers to undertake a revision of the Fossil Balanomorph Barnacles from India and the East Indian Archipelago (*Rec. Geol. Surv. India*, vol. liv). Five species in all are described, three being new, but amongst them the *Balanus tintinnabulum*, of Linné, although often cited in literature, was not to be found, notwithstanding its occurrence in the modern Indian Ocean fauna. One of the new species, *Balanus javanicus*, is closely allied to a recent South African form, and another, *B. indicus*, to a North Pacific species.

INDIAN TERTIARY GASTROPODA.—A fourth, and unhappily last, contribution on Indian Tertiary Gastropoda comes from the pen of Mr. E. Vredenburg, who did not, alas, live to revise the proofs. This part includes the Olividæ, Harpidæ, Marginellidæ, Volutidæ, and Mitridæ (*Rec. Geol. Surv. India*, vol. liv.), and is on the same lines as its predecessors (*cf.* NATURE, May 6, 1922, p. 594). Most of the species described are new and nearly all are excellently illustrated. By an oversight the pre-Linnean name Turricula of Klein, 1753, has been allowed to stand in lieu of Vexillum, Bolten, 1798.

THE GEOLOGICAL EXPLORATION OF AFRICA.—The progressive work of the Geological Survey of Nigeria has already been referred to in NATURE (vol. 110, p. 91, 1922). The fourth of the quarto bulletins, on "The Northern Tinfields of Bauchi Province," price 10s., has now been issued under the care of Dr. J. D. Falconer, and its finish and style of publication testify to appreciative Government support. The illustrations of heat-weathering and water-weathering in granite increase our knowledge of "inselbergs," and the solution-cave in the granite mass near Gohar (Pl. vi) will be a revelation to most geologists. Dr. Falconer's discussion (p. 41) of the origin of the fissures that carry tin ore in the region is of importance in the question of batholitic intrusion generally. He shows how widely spread fracturing may occur in advance of the magma rising from the depths, and how intrusive breccias result from the breaking off of abundant blocks from the zone of shattering. The tin ore may have been introduced to a large extent by vapours heralding the invasion, rather than during the cooling of the "Younger Granite" mass. In Uganda, where "mineralisation" is not obvious, Mr. E. J. Wayland is not so fortunate; he is of necessity working with a temporary staff, and there is a tendency to regard his Survey as a luxury. The Annual Report for 1922 (Entebbe, 1923) shows a wide range of work, including researches on water-supply, and we hope that it may be realised that a Geological Survey, with a geographical as well as a petrological outlook, forms the basis for the understanding of a country. The Geological Survey of Tanganyika Territory, under Dr. E. O. Teale, has issued (1922) what is called a "Final Report," in which details of mineral samples are given, together with some new points as to the Karroo flora of the district. The recommendations show that hopes are entertained of the establishment of a permanent Survey Department.

CONTACT ANGLES IN CAPILLARITY.—The modern industry of ore flotation has its origin in some of the comparatively obscure laws of surface tension, and any observations which throw light on these laws help to provide the industry with a firmer scientific basis. Mr. R. Ablett's paper in the August issue of the *Philosophical Magazine* deals with variation of the contact angle of water with paraffin wax according to whether the solid is stationary or is moving into or out of the water. The wax is in the form of a horizontal cylinder immersed to such an extent that the two liquid surfaces at its sides are horizontal right up to the solid. The angle of contact is then $104\frac{1}{2}°$. On rotating the cylinder about its axis, the angle at the side where the wax enters the water becomes 113° and where it leaves the water 96°, the wax as it were dragging the meniscus with it. For speeds exceeding 4 mms. per second these angles are constant. The author ascribes the change of angle to absorption or inhibition of the water by the wax.

THEORY OF SHIP WAVES.—A contribution to this subject, by Einar Hogner, has been published in the *Arkiv för Matematik, Astronomi och Fysik*, Band 17, No. 12. (Stockholm: Almquist and Wiksells Boktryckeri A.-B.; London: Wheldon and Wesley, Ltd.) The aim of the paper is to investigate mathematically the waves produced by a "forcive" travelling with uniform velocity over a water surface; the investigation being confined to the waves in the vicinity of two boundary planes radiating from the "forcive" and forming an angle of 19°-28′ with the mid wake plane. The author briefly reviews the mathematical explanation of the system of ship waves developed by previous authors, and points out that the theory so developed is valid only for waves at great distances from the ship, and fails in proximity of the boundary planes, where the wave amplitudes become infinite. Furthermore, no waves exist outside the boundary planes, as the approximations introduced make the surface discontinuous at the boundaries. From his modified mathematical treatment, which is given in full, the author deduces that the resultant wave system inside the boundary planes can be considered as constituted by the superposition of two different wave systems, the "transverse" and "divergent." These two systems have a phase difference of 1/3rd of a wave length at the boundaries,—a fact not hitherto noticed by previous writers on this subject. The highest points of the outermost waves are finite and situated at some distance inside the boundary planes, and the resultant wave crests form angles of 56°-44′ with the mid-water plane. The resultant wave systems inside and outside the boundary planes join without discontinuity. The system outside the boundary planes is simple. The mutual situation and direction of the crests of the different wave systems at the boundary are in general found to be dependent on the acceleration of gravitation, velocity of the forcive, and distribution of pressure within the forcive; and the direction depends also on the distance from the forcive.

The Earth's Magnetic Field for 1922.

By Dr. LOUIS A. BAUER.

THE precise constitution of the earth's magnetic field at any one time, and the causes of the constituent fields, are problems of fascinating interest, the solution of which appears destined to reveal hitherto unknown properties of matter. A most intimate knowledge of the earth's magnetic and electric phenomena, as well as a thorough acquaintance with all the latest developments of theoretical physics, seems requisite to success in the proper interpretation of the mysteries presented. Whatever theory is advanced, either for the earth's magnetic or its electric field, a hypothesis must be introduced somewhere implying new properties of matter, or changes in the classical laws of electro-dynamics, or physical conditions below or above the earth's surface, of which we have no knowledge at present. This being so, it behoves us to keep an open mind with regard to any new magnetic or electric phenomena which may come to light.

We fortunately have now three bodies, vastly differing from one another in their physical constitution, the magnetic and electric fields of which may come within the scope of our investigations and help us in our theoretical views, namely—the earth, the atmosphere, and the sun. To anticipate, we now know that the direction of the magnetic axis of each one of these bodies is related in the same way for all three to the direction of rotation of the body, and that the magnetic axis of each is inclined to the axis of rotation, namely, at present, about 11·5° for the earth, about 14° for the atmosphere, and about 6° for the sun. If f be the physical factor, ω the angular velocity of rotation, r the radius, and D the density of the body, then the strength of the magnetic fields of these three bodies, at their magnetic poles for example, may be expressed approximately by a formula of the following type:

$$F = f.\omega r^2 D.$$

The magnetic field expressed by (1) has thus far defied laboratory detection, because of the size and speed of rotation of bodies we may experiment with, but it becomes readily appreciable when we are dealing with a body of mass, size, and angular velocity of rotation comparable with those of a member of our solar system. If (1) holds universally, Jupiter, for example, would be enveloped by a magnetic field of about the same strength as that of the sun. Thus we may have to look for assistance in making notable advances concerning the structure and properties of matter to experiments performed by Nature at large.

The chief questions pertaining to the earth's magnetic field may be stated as follows: (*a*) Is any appreciable portion of the magnetic force observed on the earth's surface to be referred to a non-potential system N? (*b*) Is there, besides an internal magnetic potential system, I, also an appreciable external magnetic potential system, E, existing in our atmosphere? (*c*) If measurable N- and E-systems are disclosed, may any portions arise from relativity effects, R? (*d*) Is the integral of $d\mu$ over the earth's surface and for all constituent systems equal to zero, where $d\mu$ represents the elemental quantity of magnetism, or any other corresponding physical quantity that may evoke a magnetic field? (*e*) What physical conditions must the causes for the various systems fulfil to account for the geographic variations, the secular and other variations?

Any theory of the earth's magnetism and electricity will have to give a complete and satisfying account of these various questions before it can be accepted. Doubtless for some time to come we shall have to be content with trying out working hypotheses and must not permit ourselves to be bound to any one theory. However, encouraging progress has been made, and the object of the present communication is to tell of answers more or less complete to some of our questions.

While the magnetic survey of the globe has been in progress by the Carnegie Institution of Washington and other organisations during the past eighteen years, the writer has published the results of various investigations preparatory to a rigorous and complete analysis of the earth's magnetic field. It thus became possible to decide in what regions of the earth the field work should be intensified, and what additional allied scientific data should be included in the observational programme. Furthermore, to satisfy practical demands for magnetic data, our observational work was so arranged that sufficiently accurate results for magnetic charts could be supplied to leading hydrographic establishments within a few months after the observations had actually been made. Thus for the 1922 magnetic charts of the British Admiralty, as constructed at the Greenwich Observatory, Sir Frank Dyson states that all available material was used, "the greatest source being the observations made by the *Carnegie* and the land observations of the Carnegie Institution of Washington."

Pending more accurate and complete reduction of all observations to a common epoch by the Department of Terrestrial Magnetism than was possible by Greenwich Observatory, a preliminary analysis of the earth's magnetic field for 1922, on the basis of the latest charts and observations, was made by the writer, with the assistance of various members of his staff. The chief results were announced in a lecture entitled "The Greater Problems of the Earth's Magnetism and their Bearings on Astronomy, Geology, and Physics," delivered at the Carnegie Institution of Washington on November 21, 1922. Some later results were also presented at the meetings of the American Physical Society and the American Astronomical Society at Boston on December 30 and 31, 1922.[1] The analysis was made free as possible from assumptions as to the systems composing the entire magnetic field, and was restricted, for the time being, to the region of the earth (86 per cent.) between 60° N. Lat. and 60° S. Lat. Treating the earth as a spheroid of revolution, spherical harmonic series to the sixth degree, and in some cases to the seventh, were established separately for each of the rectangular components: X, positive towards north; Y, positive towards east; and Z, positive towards nadir.

The magnetic data utilised apply in general to longitude-intervals of 10° and latitude-intervals of 5°. Before the polar caps may be safely included in the analysis, the available magnetic data for these regions will require careful examination, and it may be found necessary to await additional data. Some analyses were also made for the regions 30° N. Lat. to 30° S. Lat., and 45° N. Lat. to 45° S. Lat. *There is evidence that the Gaussian coefficients defining the earth's magnetic field, are to be regarded at first as purely empirical quantities and, hence, strictly applicable only to the region of the earth from which they were derived.* It would seem, however, that inclusion of the polar caps will not materially alter the main conclusions given here.

The chief conclusions from our analysis are as follows:[2]

1. For a satisfactory representation of the observed data, it is necessary to recognise the existence of an

[1] *Phys. Rev.*, March 1923, pp. 370-371 and 388; also *Pop. Astr.*, March 1923, p. 186.

[2] For fuller details the interested reader may be referred to *Terr. Mag. and Atm. Elect.* for March-June (pp. 1-28), and September 1923.

internal magnetic system, I, an external system, E, and a non-potential system, N, or of three equivalent systems, X, Y, Z. The I-system constitutes about 94 per cent. of the total magnetic field, and E and N, each about 3 per cent. (There is a possibility that relativity effects, R, may play a part in the exact evaluation of the three systems.)

2. As a resultant effect of all systems causing the secular variation of the earth's magnetism, the north end of the magnetic axis of the I-system during the past eighty years has been moving slowly towards the west, and apparently at the same time slowly towards the equator. The indications from all available data are that if the magnetic axis completely revolves around the axis of rotation, regarding the possibility of which there may be some doubt, the period would not be some hundreds of years, but many thousands of years. The magnetic secular variation results from changes, with lapse of time, both in the direction of magnetisation and in the intensity of magnetisation; the latter quantity has been steadily diminishing during the past eighty years at the annual average rate of about 1/1500 part.

3. A suggestive effect, dependent apparently upon the distribution of land and water, has been disclosed, namely, that the average equivalent intensity of magnetisation for corresponding parallels north and south, is generally larger for the land-predominating parallel than for the ocean-predominating parallel. The secular changes, however, are on the average larger per annum for the south, or ocean-predominating, hemisphere than for the north, or land-predominating, hemisphere.

4. For the earth's internal uniform magnetic field, the following data apply for 1922. The magnetic moment, M, is $8{\cdot}04 \times 10^{25}$ C.G.S.;[3] the components of M, respectively parallel and perpendicular to the earth's axis of rotation, are, $M_p = 7{\cdot}88 \times 10^{25}$ C.G.S., and $M_e = 1{\cdot}60 \times 10^{25}$ C.G.S.; $M_p = 4{\cdot}93\ M_e$. Were the earth's magnetism uniformly distributed throughout the earth, which is not likely, the average intensity of magnetisation would be 0·074 C.G.S. The magnetic axis intersects the North Hemisphere in latitude 78° 32′ North and longitude 69° 08′ West of Greenwich.

There has recently appeared an account of an analysis of the earth's magnetic field, also for 1922, by Sir Frank Dyson and Prof. H. H. Turner.[4] These authors reach conclusions which apparently are at variance with mine given in (1) as to the definite existence of the two systems, E and N. However, a critical examination of the residuals obtained by them when they endeavour to represent the rectangular components, X, Y, Z, on the hypothesis of a magnetic potential due alone to systems below the earth's surface, and assuming that a non-potential system does not exist, is found, in fact, to strengthen my conclusions.[5]

Question (*a*) (*Non-potential System, N*).—The existence of the N-system implies the non-vanishing of the line integral of the magnetic force taken around a closed circuit on the earth's surface. Such line integrals have been computed for large land areas, like the United States, and for very large ocean areas, with data from the cruises of the *Carnegie*, both in the Northern and Southern Hemispheres. The results are so consistent that they cannot be accounted for wholly by observational errors. The analysis of the earth's magnetic field shows that the coefficients derived from the east-west component, Y, will not give an entirely satisfactory representation of the north component, X. A similar experience has been encountered in recent analyses of the diurnal variation of the earth's magnetic field, of magnetic disturbances, and of eclipse effects. Thus the evidence is in favour of the existence of non-potential magnetic systems. The difficulty has been in the adequate *physical* interpretation of the results. According to classical theory, line-integral values are a measure of electric currents passing perpendicularly through the area enclosed by the circuit. The average strength of such indicated currents for the earth's magnetic field is found to be more than 10,000 times that of the vertical conduction current of atmospheric electricity. The average strength of vertical currents that may in part be responsible for the magnetic diurnal variation is about 2000 times that of the currents causing the diurnal variation of atmospheric electricity. We are then forced to conclude that the magnetic line-integrals are a measure of something else than is recorded by atmospheric-electric instruments. Various suggestions are at present receiving careful consideration. The very interesting point was recently raised by Sir Arthur Schuster that no one, so far as he knew, had experimentally verified the generally accepted hypothesis that the magnetic force was accurately at right angles to the current which produced it, and he further remarked that he had very recently come across the statement that according to Einstein's theory the force and the current should not be exactly at right angles. But there are at present difficulties in trying to attribute the observed non-potential effects wholly to such a possible relativity cause.

The general system of vertical currents for the earth's field is as follows: negative electricity flowing into the earth in polar regions and flowing out in lower latitudes; for positive electricity these directions would of course be reversed. The system of vertical currents is unsymmetrical both about the axis of rotation and the equator. (A similar system of vertical currents will explain the present facts of the annual variation of atmospheric electricity.) Enough has been said to show of what extreme interest the final elucidation of the magnetic non-potential effect is likely to be.

Question (*b*) (*External Potential System, E*).—This system is disclosed by the fact that the coefficients determined from the horizontal components, X and Y, will not reproduce completely the vertical component, Z, but will leave outstanding effects of a character which, according to classical theory, can only be explained by an external system of electric or magnetic forces. However, if any portion of the earth's total magnetic field is to be attributed to causes which involve relativity effects, R, then E, in whole or in part, may have to be regarded as resulting from R. It is hoped that a special investigation now under way will throw further light on this interesting question.

As the result, apparently, of the extensive increase in knowledge of the earth's magnetic field over that at the command of previous analysts, the coefficient of the first degree zonal harmonic is found to be three times that resulting from Schmidt's careful analysis for 1885. The magnitudes of Schmidt's coefficients for the various zonal harmonics were such that he did not deem it safe to draw a definite conclusion as to the reality of an external system. The case is different, however, for our 1922 analysis; as stated under conclusion (1), we can no longer ignore the existence of effects similar to those from an external system.

Question (*c*) (*Relativity Effects*).—This question has already received some attention in the consideration of questions (*a*) and (*b*); it also enters into question (*d*).

Question (*d*) (*Is the Integral of $d\mu$ Zero?*).—All analysts beginning with Gauss have assumed that the integral of $d\mu$ is zero. The assumption enters not only into the determination of the coefficients of the

[3] The value of the magnetic moment frequently found in text-books, as dependent on Gauss's analysis for 1830, is $8{\cdot}55 \times 10^{25}$ C.G.S. The average annual rate of loss between 1830 and 1922 is about 1/1500 part, thus corresponding with the annual average rate as given in (2).

[4] Mon. Not. Roy. Astr. Soc., Geophys. Sup., vol. i. No. 3, May 1923, pp. 76-88.

[5] *Terr. Mag. and Atm. Elect.* for March-June 1923, pp. 24-28.

Z-series, but may also require consideration in the derivation of the coefficients of the X-series and of the Z-series, if there is a non-potential system N. So far as the Z-component is concerned, if we do not assume the integral to be zero, a small constant term is added to the Z-series, which slightly improves the mathematical representation. If we have an N-system caused by vertical currents, as already described, then the question arises whether for a limited portion of the earth, for example from 60° N. Lat. to 60° S. Lat., we may legitimately assume that the total amount of electricity leaving the earth equals the total amount entering it in this region; if not, then $\int d\mu$ would not be exactly zero. It is of interest to note that Gauss himself intimated, in his celebrated memoir on the "General Theory of the Earth's Magnetism," that the day might come when it could not longer be assumed that the integral of $d\mu$ is zero. Investigations in progress will further elucidate this matter.

Question (*e*) (*Variations of the Earth's Magnetic Field*).—We now come to crucial tests that may be applied to any theory of the cause of the earth's magnetic field. It would seem as though the surest approach to a solution of the two problems, the origin of the earth's magnetic field and the origin of the earth's electric field, will be by means of the striking variations, geographic, diurnal, annual, sun-spot, and secular, to which they are subject. The two chief sets of variations, which a theory of the earth's magnetic field will have to explain satisfactorily, are: (1) the geographic variations; (2) the secular variations.

Fig. 1 is intended to show how ρ, the equivalent intensity of magnetisation or any other corresponding physical quantity, would have to vary from parallel to parallel in order to produce the portion (about 70 per cent.) of the earth's total magnetic field symmetrical about the axis of rotation, as represented by zonal harmonics to the sixth degree inclusive. If this portion of the field were uniform, then ρ, represented by the radius-vector from O, would be constant; this case is shown by the outer circle. Were the zonal field symmetrical about the equator, then instead of the outer circle we have an ellipse, which has been drawn for each of the two epochs 1885 and 1922 (indicated by broken curves); for this case ρ for the equator would be about 17 per cent. greater than for the combined parallels 60° N. and S. The heart-shaped full curves represent the actual state of affairs for the field symmetrical about the axis of rotation. Comparing the radii vectores, ρ, for corresponding parallels of latitude, north and south, it is seen that for both curves (1885 and 1922) ρ is invariably greater for a land-predominating parallel than for an ocean-predominating parallel, and this fact obtains even for the dotted portions of the curves which apply to the polar regions (see conclusion 3.) It will be noticed that the 1922 heart-shaped curve lies wholly within the 1885 one, just as was the case for the ellipses, and the difference, $d\rho$, between the curves represents, proportionately, the shrinkage in the earth's magnetic moment, or in the equivalent intensity of magnetisation, between 1885 and 1922. It will be noticed that the shrinkage is greater for the south, or ocean-predominating, hemisphere, than for the north, or land-predominating, hemisphere. The effect of the distribution of land and water is one calling for careful examination, and its further study may result in material advancement of our knowledge as to the cause or causes of the earth's magnetic field.

If we wish also to take into account the balance of the earth's magnetic field, about 30 per cent., which is unsymmetrical about the axis of rotation and is represented by the tesseral harmonics, then the pear-shaped solid, obtained by the revolution of the heart-shaped curve about the earth's axis of rotation, would have an irregular surface with specially pronounced humps at the magnetic poles. The radius vector to this somewhat irregular pear-shaped solid would serve to represent the volume or surface distribution of the physical quantity entering into, or evoking, the observed magnetic field. It is clear that no approximately homogeneous spherical iron core inside the earth could produce such a magnetic field as that actually observed.

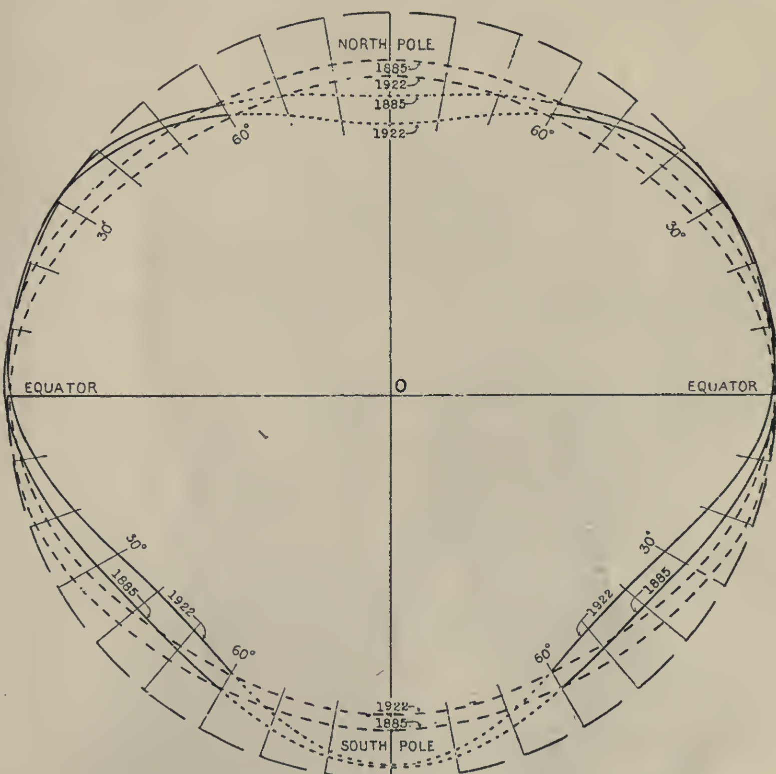

FIG. 1.

Now consider the shrinkage in the earth's magnetic moment. The average annual rate of shrinkage was 1/1000 part between 1885 and 1922;[6] it was found to be 1/2170 part between 1890 and 1900, and about 1/2580 part between 1843 and 1883.[7] Whether the annual rate of shrinkage varies as greatly from time to time as is apparently indicated by these figures is open to question and subject to further investigation with sufficiently trustworthy magnetic data. The steady diminution in the strength of the earth's magnetic field, averaging during the past 80 years about 1/1500 part annually, presents one of the greatest difficulties in the theory as to the cause of the earth's field, the surmounting of which may prove to be the key to the sought-for secret. It should be borne in mind that the annual loss is

[6] *Terr. Mag. and Atm. Elect.*, March-June 1923, pp. 15, 22, and 23.
[7] *Terr. Mag. and Atm. Elect.*, vol. 9 (1904), p. 183.

quite comparable with that of well-seasoned magnets. The loss occurs practically all in the uniform portion of the earth's magnetic field, parallel to a diameter, inclined at present to the axis of rotation about 11·5°; the loss is not made up by any material gain in the non-uniform, heterogeneous portion of the earth's magnetic field.[8] The annual percentage loss is nearly the same for the polar and equatorial components of the uniform magnetic field; and as the equatorial component is only about one-fifth that of the polar component, the absolute annual loss in the earth's magnetic moment results almost entirely from the polar component, *i.e.* the uniform portion of the earth's magnetic field, symmetrical about the earth's axis of rotation, suffers nearly the entire loss.

The system of forces which must be superposed upon the uniform internal magnetic field of 1885 in order to obtain the observed field for 1922 proves to be a demagnetising system, the magnetic axis of which is directed almost diametrically opposite to that of the primary uniform field. A similar result was found in 1904[9] for the period 1890–1900. In brief, the secular-variation system shows the characteristics of the self-induced field of a uniformly magnetised body.

Let us next inquire briefly into which of the quantities in formula (1) so large an annual rate of change for the earth's field as 1/1500 part is to be attributed? Certainly not to the angular velocity, ω, or to the radius, r, or to the density, D, since changes on the order of 1/1500 part in one of these quantities, or in their combined product, would not escape detection by other means. We must conclude that the physical factor, f, contains within itself the kernel for the observed change, but what does this imply?

Let us suppose next that in the factor f we have embodied some physical relation upon which both the earth's magnetic field and its gravitational field depend. Then on the basis of the large average annual loss during the past eighty years in the strength of the earth's magnetic field, we can immediately say that magnetism and gravity are not related to each other as the first power of the factor, for otherwise a correspondingly large annual change in gravity would likewise have been observed. Again, while gravity is greater over the oceans than over continents, the equivalent intensity of magnetisation is, on the average, somewhat less for ocean areas than for continental areas, so here again there is no immediate relation between gravity and magnetism. According to Sutherland's theory[10] which was based on a slight modification of the laws of electrodynamics, magnetism would depend on the first power of a small fraction β (about $2·6 \times 10^{-22}$), and gravity upon the second power; this quantity β would enter into the factor f of formula (1). Accordingly the annual decrease of 1/1500 part in magnetism would imply, on Sutherland's theory, only a decrease of the square of 1/1500 part, or about one-half of a millionth part in gravity, and this is a quantity which may readily escape detection with our present gravity appliances, unless the accumulative effect over many years be carefully observed at several standard stations. Hence, a theory involving gravity and magnetism in the manner prescribed by Sutherland's hypothesis might be admissible. But the observed decrease in the earth's magnetic field-strength would then have to be referred to a corresponding change in β. But what makes β change? It was only meant to represent a very slight variation in the law of action between electric charges; if β changes, so must the new assumed law of electro-dynamics. We have under investigation various hypotheses to account for the observed secular changes in the earth's magnetic field.

Sufficient has been given to show with what extreme care a theory of the earth's magnetic field will have to be formulated and how exhaustively it will have to be examined in the light of the data now known to us. No one who will familiarise himself with the facts will lightly announce the discovery of a new theory of the origin of the earth's magnetism. New and interesting matters may confidently be expected from the discovery of the true cause.

FIG. 2.

In conclusion, Fig. 2 is presented to show the positions of the following points: MA(I), north end of magnetic axis of the earth's uniform internal magnetic field in 1922, latitude 78° 32′ N., and longitude 69° 08′ W.; MA(E), north end of magnetic axis of the earth's uniform external magnetic field in 1922, latitude 76·8° N. and 121·4° W.; and N.M.P., the approximate position of the North Magnetic Pole in 1904, latitude 70·5° N., and longitude 95·5° W. As will be seen, the line of maximum auroral frequency passes to the south of the three positions. (The other lines shown are the routes of the *Carnegie*.) It will be noticed that the displacement of the E-axis is about 52° west of that of the I-axis, and that the N.M.P. is about midway in longitude between I and E. From the amount and direction of displacement of the E-axis with reference to the I-axis, we may deduce further important facts bearing upon the theory of the earth's magnetic field and the possible conductivity of interplanetary space.

Lichens and their Action on the Glass and Leadings of Church Windows.

By Dr. ETHEL MELLOR, University College, Reading.

THE gradual deterioration and destruction of the stained glass of church windows is a subject of general and scientific interest. It will, therefore, probably be admitted that the technical and practical knowledge of the stained glass artist should be reinforced by the theoretical and laboratory studies of the scientific worker. One of the several possible lines of research was approached nearly three years ago at the Sorbonne under the direction of the late Prof. Matruchot and afterwards of the late Prof. Bonnier.

FIG. 1. (×36.)

(*a*) Opaque discs with beginnings of pits; (*b*) pit bordered by opaque glass.

The deteriorated glass is scaly and iridescent, or pitted and opaque. Both surfaces are attacked, and though the outer shows the greater alteration, it is on the inner that the action is sometimes first apparent. The opacity may extend over the whole surface, but more frequently appears as scattered disc-like points; these gradually get bigger and frequently run together. Meanwhile, the glass at the centre of the original opaque discs disappears and so arise the beginnings of the pits, each bordered by opaque glass and later lined by iridescent scales visible under the binocular lens. As the alteration of the glass continues, the pits increase in diameter and often unite, forming channels of diverse outline and length (Fig. 1). The maximum breadth measured was 5 mm., and depth 1·9 mm. Two pits on opposite surfaces will sometimes increase in depth until the separating wall disappears and a perforation of the glass results. Microscopical examination of the opaque glass shows markings and surfaces similar to geographical contours, and the contortions and cleavages of rocks.

In some cases there is no opacity, and there are no pits. The surface is iridescent and may appear slightly irregular over more or less extended areas. The alteration here takes the form of scaling in thin horizontal plates shown under the microscope to consist of several superposed layers variously cleft and resembling a crazy-tiled garden path.

Unstained and stained glass are similarly deteriorated, but certain colours show more susceptibility to alteration than others. Purple, green, blue, red, amber, and particularly amethyst glasses, are all deeply corroded, while grey tones are less so, and the golden-yellow glass resulting from the vitrification of the silver salts is more or less immune. This immunity is well illustrated in the reproduction of a fragment of fifteenth-century glass (Fig. 2); the surface of the grey and colourless portions is corroded and opaque, and outlines clearly the golden-yellow border and leaf.

There is little reason to believe that the glass of any century is the more frequently or gravely attacked. The glass of the twelfth to the fifteenth centuries is more refractive than that used later and shows a slower rate of alteration, but the cumulative destructive effects are great. The extent of the corrosion does not depend upon age—portions of fourteenth-century glass are still unaltered; specimens of nineteenth-century glass are sometimes badly pitted. The corrosion is of considerable importance æsthetically, but, though it continue until perforation occurs, it does not affect the actual duration of the window; this depends upon the leadings.

The oldest leadings are heavy and have well resisted chemical change; the lighter lead used since the fifteenth century is much more liable to conversion into carbonate of lead, friable and unstable. The transformation is often completed in less than fifty years. This is a matter of supreme importance, for the leadings constitute the skeleton of the window and their appearance remains reassuring after the chemical change has taken place. They are, however, no longer solid, and the crucial moment arrives when an external condition, such as a gust of wind, causes them to disaggregate and allow the glass to fall. It is in this way that so many of the marvellous windows of the last few centuries have perished. This destructive process has been studied and pointed out repeatedly during the last thirty years by M. Félix Gaudin of Paris, a well-known *peinte-verrier*; it cannot be emphasised too much that it is through the leadings and not through the glass that historic windows are often lost.

The alteration of the lead is purely chemical; that of the glass is due to two causes, chemical and mechanical. Strange though it may seem, the windows serve as a substratum for lichens. These plants retain water between their tissues and the glass by capillarity; they also find favourable conditions for growth in proximity to the leadings, which check the drainage where they approach the horizontal plane, and when loose hold water. The amount of carbon dioxide normally dissolved in water is considerably increased by that evolved by the lichens

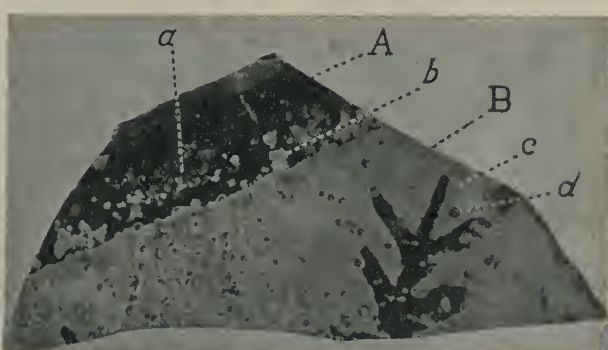

FIG. 2. (Natural size.)

A, Golden-yellow glass: (*a*) scaly glass; (*b*) opaque glass. B, Grey and colourless glass: (*c*) opaque surface; (*d*) pit.

during the process of respiration, and the chemical change of glass and lead is thus accelerated. Evidence of this augmentation of the chemical action is given by the opacity and squamosity of the glass closely following the track of the lichen.

The mechanical action of the lichens accounts for the disappearance of the opaque glass, and the consequent formation of pits and channels. The minute fissures in the opaque glass are penetrated by the lichen hyphæ, which by their varying states of

turgidity, and increase in length and number, loosen the particles and eventually incorporate them in their tissue. The inclusions, always microscopic, occur chiefly in crustaceous thalli below the apothecia and spermogonia, and in the rhizoids of the foliaceous thalli. Vertical sections of the thallus of a *Pertusaria leucosora* Nyl. contained numerous inclusions throughout the lower 0·4 mm. of their thickness.

The inner surface of the glass is the one most frequently squamose. The conditions here are most unfavourable for the development of lichens and usually there is no delimitation of the thallus. The

FIG. 3. (×36.)
(*a*) *Placodium murorum* DC. and circular pit; (*b*) corrosion showing outlines of original pits.

lichen constituents, hyphæ and gonidiæ, are not associated in a definite tissue but exist as a thin layer, resembling a cobweb, over more or less the whole surface, which shows a similar extensiveness in its alteration. Hyphæ and gonidiæ pass between the scales of glass, the former the more deeply, and incorporation follows.

The lichen flora of church windows is practically confined to the exterior, and necessarily limited by the exposed and slippery substratum. Twenty-three species and varieties have been identified, including only one fructaceous, *Ramalina polymorpha* Ach. var. *ligulata* Ach., and two foliaceous, *Xanthoria parietina* Ach. and its variety *tumida* Wed. All the others are crustaceous, these being the best adapted to the environment. There appears to be a succession in the flora analogous to that on a larger scale of the flora of dunes in so far as there is a preparation of the substratum for subsequent species of lichens. A crustaceous species, *Diploicia canescens* Ach., is the most abundant but it rarely occurs except on the unaltered glass; its thallus, of a maximum diameter of 4·6 cm., disappears and leaves a slightly roughened surface. Other crustaceous species follow, two varieties of *Placodium murorum* DC. being most interesting, showing as they do a conformity between their disc-shaped thalli and the circular pits of their substratum (Fig. 3). The crustaceous lichens apparently cease to thrive once the glass becomes deeply corroded, yet it is on this considerably altered surface that the fructaceous and foliaceous species exist (Fig. 4).

The lichens are not well developed. Some are not visible to the naked eye; the thallus is small, mal-formed, incomplete, or greatly sorediﬁed; apothecia are frequently absent or, conversely, persist longer than the thallus. Their determination is difficult, and is often only possible through a prolonged and concentrated study of the gradual change undergone by a species.

Lichens need plenty of air and a certain humidity, with little wind or sun, for their free growth; consequently, windows with a south aspect in the country and all windows in a crowded neighbourhood are unfavourable substrata; they have a scant flora or none at all, and show little deterioration. On windows with a west or north aspect, in humid, calm, but airy surroundings, lichens multiply abundantly and quickly, and the glass shows a correspondingly high degree of alteration. The colour or chemical composition of the glass probably influences the development of lichens, as it is not unusual to see glass of one colour bearing many of these small plants while adjacent glass of another colour is free.

Growth of lichens on windows can be prevented by the simple means of regularly brushing and washing the windows, or by the application of a liquid mastic to exclude air and lichen spores. The essential condition for the ultimate preservation of the windows is that the leadings should receive constant attention and periodic renewal.

The material examined has in the bulk been collected by M. Gaudin throughout Brittany, Normandy, Champagne, Ile-de-France, etc. A certain number of specimens from the Mayenne churches submitted by M. Alleaume, *peinte-verrier* of Laval, are now deposited in the museum of that town.

The Liverpool Meeting of the British Association.

LOCAL ARRANGEMENTS.

AN elaborate programme of excursions to places of interest and visits to works has been arranged by the Local Committee. Dealing first with the general excursions, on Thursday, September 13, it is intended that a visit shall be paid to the biscuit works of Messrs. W. and R. Jacob and Co., Ltd., to the United Alkali Works at Widnes, the flour-mills of Messrs. W. Vernon and Sons, Ltd., and the Liverpool Corporation electric power-station, when some of the largest and most up-to-date plant will be inspected. The White Star Line is also inviting a party to view the s.s. *Adriatic*. On Friday, September 14, visits are arranged to Messrs. Bryant and May's match works, to the dyeing and cleaning works of Messrs. Johnson Bros., Ltd., and to the shipbuilding yards of Messrs. Cammell Laird and Co., Ltd. The Cunard Steamship Co. is inviting a party to inspect the s.s. *Franconia*.

On Saturday, September 15, there will be a whole-day excursion to Chester and the River Dee, including a visit to Eaton Hall, by kind permission of the Duke of Westminster. Another whole-day trip will be to the Dolgarrog works of the Aluminium Corporation, Ltd., the party, after inspecting the works, proceeding to Bettws-y-Coed and the Snowdon district. A visit, also occupying the whole day, has been arranged to the Liverpool Waterworks at Lake Vyrnwy.

Of a more general type there will be a day excursion to the Isle of Man, and also by sea to Llandudno and Beaumaris. There will also be a two-day tour (Saturday and Sunday) to the Lake District. On Sunday, September 16, there will be a general excursion by sea to Llandudno and Beaumaris.

On Monday, September 17, visits will be paid to one of the works of the British Insulated and Helsby Cables Co., Ltd., Messrs. Lever Bros.' Soap Works at Port Sunlight, and to the works of Meccano, Ltd., and to the Union Cold Storage, Ltd. A party will also be shown the Liverpool housing scheme, and the Liverpool Salvage Association is inviting those interested to view their plant. The Booth Steamship Co., Ltd., is inviting a party to inspect the s.s. *Hildebrand*.

On Tuesday, September 18, a party will visit the Gladstone Dock and other works of the Mersey Docks and Harbour Board, the Llay Main Colliery near Wrexham, Planter's margarine works at Bromborough Pool, and the large bobbin works of Messrs. Wilson Bros. at Garston.

Of the sectional excursions at present arranged, Section A will visit the Automatic Telephone Manufacturing Co., Ltd., the British Oxygen Co. (Bootle works), and Stonyhurst College; Section B, the United Alkali Co.'s works at Widnes, the Highfield Tannery at Runcorn, Price's Patent Candle Co. at Bromborough, the lactose factory at Haslingden near Crewe, and Messrs. Joseph Crosfield and Co.'s works at Warrington.

Section C will go to Hall Road and Crosby on the north of Liverpool, Storeton Quarries, Burton Point and North Wirral, Lake Vyrnwy district, parts of Flintshire, the Lea Green Collieries and Brick Pits, and Scarth Hill and Skillaw Clough.

Section D is proposing to go a dredging expedition in Liverpool Bay, and to Delamere Forest. Section E is visiting the Liverpool Docks, Storeton, Burton Point and North Wirral, and a river trip to the Eastham Locks of the Manchester Ship Canal, and down the Mersey to the Crosby Channel.

Section F intends to visit the Liverpool Docks and the Cotton Exchange. Section G has arranged one excursion only, and that is to the Gladstone Dock. Section H will inspect the Roman remains at Chester, and will also visit Ince Blundell.

Section I has arranged no sectional excursions.

Section J has one excursion only, namely, to Rainhill, where the County Lunatic Asylum is situated.

Section K is planning to visit the Craven limestone district, Mr. Bulley's gardens at Neston, and the West Lancashire sand dunes near Freshfield. Section L has arranged no excursions. Section M will visit Wirral Farms and Messrs. Gartons, Ltd., at Warrington, and Haslington and the Nantwich district.

Large as this list of sectional excursions appears, if one is to judge from the experience of previous meetings it will be found to have increased by the date on which the meeting commences.

A list of all these excursions and visits will be sent, a short time before the meeting, to members who have intimated their intention of coming to Liverpool, and it will greatly facilitate the work of the Local Secretaries if members will intimate in advance which excursions they would wish to join.

At the close of the meeting in Liverpool there will be an excursion to the Isle of Man, leaving Liverpool on Wednesday, September 19, and returning on Monday, September 24. The party will have an opportunity of visiting all places of scientific interest in the island, but probably members of Sections E and H will find most to study. A special committee in the Isle of Man is making all arrangements, and details will, it is hoped, be completed by the opening day of the meeting in Liverpool.

Although perhaps it does not so much concern the actual members of the Association, yet a definite item in the programme of the meeting is the series of public lectures. The number of these it is proposed to give in Liverpool will be greater than in any town previously visited by the Association, and further, one will be given in Bootle, Wallasey, Birkenhead, Runcorn, Warrington, Wigan, and, St. Helens, while two lectures to young people will be given in Liverpool and one in Birkenhead and Warrington. It is the hope of the Local Committee that these lectures will prove a great success, and so develop one of the prime objects of the Association, namely, to promote interest in science and its applications. ALFRED HOLT.

International Hydrography.

MANY abortive attempts were made before the War to found an international hydrographic organisation, but success was not achieved until after the War, when a conference was held in London, in 1919, at the invitation of the British Admiralty, with the cordial support of the French hydrographic office. Twenty-one states were represented at the conference, invitations having been sent to all countries likely to be interested, with the exception of the Central Powers, Russia, and Turkey. As a result an International Hydrographic Bureau was instituted in 1921, and all the States represented at the conference have now associated themselves with it. The Bureau has its official seat at Monaco. Soon after its institution it became affiliated to the League of Nations, and it uses the official languages of the League, namely,

English and French. Its three chief officials are Sir J. D. Parry (Great Britain), Admiral Phaff (Netherlands), and Captain Müller (Norway), the first-named being president. It confines itself to hydrography in the strictly nautical sense of the word, and one of its chief objects at present is the international standardisation of practice in relation to many maritime matters. For example, in relation to charts, among the questions which arise are those of the type of projection, the scale, the choice of units for depth and distance, the mode of delineation of soundings, the symbols and abbreviations, and the geographical names to be used. Lists of lights, sailing directions, and distance tables are other matters on which more uniformity and co-operation would be advantageous. It may be noted that most countries now use metric units for depth, Japan being one of the latest formally to adopt this system, though it has not yet actually introduced it. Great Britain and America are now the only States which exclusively use the fathom and foot, but the change to the metric system is one which they are as yet unwilling to make, because of the great difficulty and cost of altering the copper plates from which are printed the exceptionally large number of charts which these countries produce.

The Bureau has recently started a journal, the *Hydrographic Review*, of which the first number appeared in March last. It is bilingual, all its contents being duplicated in English and French, on opposite pages. A large part of the first issue is devoted to the history of the inception of the Bureau, and other official matters. The chief original articles consist of two reports on aerial photography as applied by the French and Netherlands services to hydrographic surveying and the discovery of shoals and covered rocks. There is also a discussion of the visibility of lights, considering the chances which a sailor has of sighting a given light in different circumstances at various distances, and a brief report on echo sounding as practised by the United States hydrographic department.

The Age of the Earth.[1]

SINCE the advent of our knowledge of radioactive processes, the old controversy over the age of the earth has been revived, and although there is now a marked change of opinion in favour of the longer estimates, it remains unfortunately true that there still appear to be tantalising discrepancies between the results from different methods. These discrepancies may be mitigated or exaggerated by special pleading, but they still stand in the way of an unequivocal settlement of the problem.

Twenty years ago various attempts were made to squeeze geological history into the narrow limits imposed by Kelvin and Tait. The discovery of radioactivity, and more recent advances in the study of stars and tidal friction, have destroyed the value of the older physical evidence, leaving various geologists committed to what are now seen to be absurdly low figures. In the last decade the geological methods have in turn been widely criticised, and the present tendency is greatly to extend the estimates formerly favoured. All the methods adopted depend on the rate of processes at present in operation. In order that the different lines of evidence should converge, it is necessary to suppose either that the rates of geological processes are at present too high, or that those of radioactive processes are too low, to justify integration over the whole duration of geological time.

In the symposium under consideration, held in Philadelphia on April 22 last year, the chief feature of interest is Chamberlin's spirited attempt to show how the geological estimates may be brought into harmony with the revised deductions from radioactivity and astronomy. The period required for the deposition of the whole of the sedimentary column or for the accumulation of salt in the oceans is easily arrived at from existing data on the assumption that present rates provide a characteristic average. There is now little doubt that this assumption is deceptive, and it certainly can no longer be admitted. De Geer's work on the yearly deposits from glacial waters in Sweden, though an exceptional case, suggests to Chamberlin a Glacial epoch fully twenty times as long as that assigned by the old methods. He further expresses the conviction that breaks in the continuity of more normal sediments, the time-values of which are best judged by comparison of the faunas above and below, must, when finally interpreted, greatly extend the simple arithmetical estimates. It has frequently been shown how denudation and deposition must be quickened up by human activities, and the effects of cultivation and excavation have been ably analysed by Dr. Sherlock in his recent "Man as a Geological Agent." Existing conditions also naturally favour a high rate of denudation, since continental elevation and breadth are both exceptional, and to these may be added the further consideration that broad areas are strewn with easily removable glacial deposits. So variable are the factors involved that there is no means of arriving at average rates which would properly include long periods of sea-transgression and base-levelling, periods when denudation was brought almost to a standstill.

The validity of the method based on the accumulation of salt in the oceans depends partly on the rate at which the present streams are carrying sodium down to the sea—a rate which must be too high for reasons already mentioned—and partly on the irreversibility of the process. It has, of course, been generally recognised that sodium returns to the land in interstitial solutions held by sediments and as wind-borne salt, but other possibilities have been less emphasised. Actually it is found that the data used are inconsistent among themselves unless other cyclic processes are involved. The most serious discrepancy is found in the ratio of sodium to chlorine, which in igneous rocks is about 30 : 1 and in the oceans about 1 : 1·8. When volcanic exhalations are taken into consideration this enormous difference is reduced but by no means wiped out. Clarke and Washington have given figures which include the whole of the atmosphere and hydrosphere, and the discrepancy still remains as high as 20 : 1.

There can be only one explanation: that chloridised sodium plays a far greater part in cyclic action than has yet been detected. In the case of potassium such circulation is all-important and is effected by its greater retention by muds and soils. Dr. Milton Whitney writes, "Ocean shore deposits would undoubtedly absorb NaCl up to the point where the colloids were in equilibrium with sea water," but as to the relative efficiency of this and analogous processes there is still no exact knowledge. The sodium method is thus, as Chamberlin says, "not yet ready to render a verdict." As to the sedimentation method,

[1] From the Geological View-point. By T. C. Chamberlin. From the Paleontological View-point. By J. M. Clarke. From the Point of View of Astronomy. By E. W. Brown. The Radioactive Point of View. By W. Duane. (Proc. Amer. Phil. Soc., vol. lxi., No. 4, pp. 247-88, 1922. Philadelphia.)

he concludes that the cumulative effects of present-day conditions need not be strained to bring the older estimates up to the same order as those required by current deductions from radioactive minerals.

The remaining papers call for little comment. Palæontology presents faint hope of arriving at a trustworthy or even approximate conclusion as to the age of the earth, for no measure of the rate of vital processes has yet been devised. The endurance of an index species provides no firm basis for a definite calculation of the duration of a zone, or *phase*. Astronomical considerations have recently afforded support to the figures suggested by radioactivity for the age of the earth, but there is here no discussion of the work and views of Eddington, Jeffreys, or Shapley. Similarly the paper on the "Radioactive Point of View" omits to mention the interesting speculations of Joly, which are so ingenious that they will demand a thorough discussion in the future, even though in the present stage of knowledge they may be coldly regarded by physicists.

Arthur Holmes.

University and Educational Intelligence.

Cambridge.—Dr. P. Kapitza, Trinity College, has been elected to the Clerk Maxwell Scholarship.

The London County Council's programme for 1923–24 of lectures and classes for teachers comprises some 600 items grouped under the headings art, domestic subjects, economics and political science, languages and literature, geography, handicrafts, history, mathematics, music, pedagogy, phonetics, physical education, science, miscellaneous. The science group includes 52 items, namely, wireless, 5 (Prof. J. A. Fleming); history of science, 10 (Dr. C. Singer); psychology of vocational guidance, 5, and the neurotic child, 5 (Dr. Cyril Burt); bacteria, moulds, and yeasts, 5 (Dame Helen Gwynne-Vaughan); mental deficiency, 6; British weather, 6 (Sir Napier Shaw); animal parasites and pests, 5 (Dr. Philippa Esdaile); and Kew Gardens, 5 (Major Chipp). Moreover, the pedagogy group includes no lectures on the teaching of science. The lectures "are designed to bring London teachers in touch with the latest developments in educational technique and to give them opportunities, as well, for coming into touch with expert opinion on questions of national and civic importance. The lectures largely reflect therefore those questions which are the subject of topical discussion." The choice of subjects is limited by the fact that the scheme has to be self-supporting, and this may be the reason why no provision is made for lectures on civics, home-economics (except a course on domestic handicraft), nature-study, or general science. The lectures are open to all teachers actually employed in teaching within London at a fee of one shilling or less per lecture, and to teachers from outside at rates 50 per cent. higher. The attendance last year was 20,000. Several scientific societies place at the disposal of the London County Council a certain number of tickets of admission to their ordinary meetings for distribution to teachers of science in London schools.

British women students wishing to spend the coming academic year studying in Paris may like to know that three residence scholarships for British graduates studying at the Sorbonne or other institution of higher learning in Paris are offered by the American University Women's Club, 4 Rue de Chevreuse. The value of each scholarship is 350 francs per month for nine months, and the rates charged by the Club are such that each scholar would need to pay an additional 500 francs a month, *i.e.* about 60*l.* for the nine months. Applicants for these scholarships should send their names, stating their age, academic qualifications and proposed course of study, to the Secretary, International Federation of University Women, 92 Victoria Street, S.W.1, not later than September 15. Each application should be supported by at least two references permitted to persons well acquainted with the candidate's career.

The use of the local environment of the school as a starting-point and source of material and interest in that school without exploiting it for vocational training is discussed in Rural School Leaflet No. 11 of the United States Bureau of Education, in which an attempt is made to show in detail how this principle should be applied in agricultural districts. It appears that in 17 states the teaching of "agriculture" in the elementary schools throughout the state has been prescribed by law somewhat precipitately, without regard to the fact that teachers with the requisite special training are not available and without any clear definition of objectives or methods. Such precipitation is, the writer points out, the more to be deprecated in view of the exceeding complexity of agriculture alike on the side of natural science, every branch of which it lays under contribution, and on the side of practice, wherein it involves not only a great variety of arts but a mode of living. At the same time this very complexity makes a naïve experience of agricultural happenings invaluable as a starting-point and source of material and interest. Dealing with the social and economic aspects of the subject, he contends that even in the elementary schools teachers should not fail (as they have failed in the past) to emphasise the necessity of the organisation of farmers as a means of economy in distribution and self-preservation in the struggle for existence in competition with other organised groups.

Developments in medical education in the United States during the past 20 years, and especially during the years 1920–22, are summarised by Dr. N. P. Colwell in Bulletin 18 of 1923 of the U.S. Bureau of Education. Since 1904, when the American Medical Association started a campaign for raising educational standards, the developments in respect of medical school admission requirements, laboratory and library equipment, number and calibre of whole-time professors, and arrangements for clinical instruction, have been such that these standards, formerly lower than those of the principal European countries, can now challenge comparison with any in the world. Simultaneously the number of schools has been reduced by one-half—from 162 to 81—and the number of students from 28,000 to 13,000 in 1919, since when they have increased to 18,000. Of 81 schools, 66, rated as class A, require two years of college work as a condition precedent to entry on their four-years' course. Although students' fees, which formerly covered the cost of maintenance of the schools, have been largely increased, they amount now to little more than one-third of the cost. Along with improvement in medical schools has gone a corresponding advance in the standard of qualifications required by state medical licensing boards, but the laws on the subject have to some extent been stultified by the existence of sectarian "schools" with low educational standards, which have not been made subject to medical practice laws although their graduates assume the responsibility of undertaking to heal the sick.

No. 2808 AUGUST 25, 1923

The Life History of an α-Particle.[1]

By Sir ERNEST RUTHERFORD, F.R.S.

IN this lecture I propose to discuss some of the properties of the high-speed α-particle which is spontaneously ejected from radioactive substances. This flying atomic nucleus is not only the most energetic projectile known to us, but it is also an agent of great power in probing the structure of atoms, so that an account of the effects produced by it is of wide scientific interest.

It is now well established that the α-particle expelled from radioactive bodies is in all cases a helium atom, or, to be more precise, the nucleus of a helium atom of mass 4 carrying two positive charges of electricity. It is only when the expelled nucleus is stopped by its passage through matter that it captures the two negative electrons required to convert it into the neutral helium atom. It is natural to suppose that the helium nucleus, which is shot out at great speed from the heavy nucleus of a radioactive atom, formed part of its structure. For some reason, which is not as yet understood, occasionally one of the radioactive nuclei breaks up with explosive violence, ejecting the component helium nucleus with high velocity. It is probable that the α-particle in escaping from the radioactive nucleus acquires part of its great energy of motion in passing through the repulsive electric field surrounding the latter, but at present we do not know the nature of the forces which hold the complex nucleus together, or whether the α-particle is at rest or in orbital motion in the nuclear structure before instability sets in. We know, however, that there is a very wide range of stability exhibited by different radioactive elements. In a substance like radium A, the average life of the radioactive atom before ejection of an α-particle is about 4·3 minutes, for radium itself 2250 years, while in the case of a very slowly changing element like uranium the average life is of the order of 7000 million years.

It is known that the α-particles from a given element are all shot out with the same speed but that this speed varies from element to element. There is apparently a close connexion between the velocity of ejection of the α-particle and the average life of the parent element. The shorter the average life of the element, the swifter is the speed of expulsion. This interesting relation between the violence of the explosion and the average life of the element holds in the majority of cases, but it is difficult at present to be at all clear of its underlying meaning. Sir William Bragg long ago showed that the α-particle travels through matter nearly in a straight line, and has a definite range of travel in a substance. This is well illustrated by the tracks of α-particles obtained by Wilson's expansion method. The majority of the tracks are seen to be quite straight, apart from an occasional deflexion near the end of the path. At the end of the range the photographic and ionising effects of the α-particle apparently cease with great suddenness. On account of its great energy of motion, the individual α-particle can be detected by the scintillation it produces in crystalline zinc sulphide, by the effect on a photographic plate, and by special electrical methods, while the beautiful expansion method of Wilson shows the trail of each individual α-particle through the gas.

We are enabled, particularly by the scintillation method, to count the individual particles, and thus we have at our command a method of great delicacy for studying the effects produced by the passage of α-particles through matter. In travelling through a gas the α-particle passes through the outer electronic structure of a large number of atoms and liberates electrons, thus giving rise to an intense ionisation along the track. The ionisation increases to a maximum near the end of the path of the α-particle and then falls rapidly to zero.

A careful study has been made of the law of decrease of velocity of the α-particle in passing through matter by studying the deflexion in a magnetic field of a pencil of α-particles before and after its passage through a known thickness of matter. In most of these experiments we employ the α-particles of radium C, which have a range of about 7 cm. in air under ordinary conditions. The initial velocity V_0 of these particles is known to be 19,200 kilometres per second, and the reduction of velocity can readily be followed down to about 0·4 V_0. At this stage the emergent range of the α-particles is less than one centimetre, and measurements are difficult, owing to the fact that a beam of α-particles becomes heterogeneous and contains particles moving with different velocities.

[1] Discourse delivered at the Royal Institution on Friday, June 15.

For this reason the velocity of the α-particle cannot be followed with certainty below 0·38 V_0. We must bear in mind that even at the lowest velocity at which it is possible to detect the α-particle by the scintillation or photographic method, it is still moving at a high speed compared with the positively charged particles generated in an ordinary discharge tube.

It is clear that ultimately the α-particle must be slowed down to such an extent that it captures electrons and becomes a neutral atom, but until recently no evidence of this process of capture of electrons had been obtained. G. H. Henderson (Proc. Roy. Soc. A, 102, p. 496, 1922) has recently added much to our knowledge of this subject by examining the deflexion of α-rays in a magnetic field in a very good vacuum. For the success of these experiments it is essential that the apparatus in which the deflexion is observed should be exhausted to a very low pressure, corresponding to that required for a good X-ray tube. The reason of this will be seen later. When a narrow pencil of α-rays was deflected in a magnetic field two bands were observed on the photographic plate, one the main band, due to ordinary α-particles carrying two positive charges, and another midway band which he supposed to consist of particles which had captured one electron, *i.e.* to singly charged helium atoms. At low velocities he also obtained evidence of the existence of neutral α-particles resulting from the capture of two electrons by the helium nucleus. In these experiments Henderson employed Schumann plates, where the film is so thin that low velocity particles produce as much or more photographic effect than the swifter particles.

I have repeated these experiments; by the scintillation method, and confirmed the deduction of Henderson. By observing the deflexion of the midway band in an electric as well as in a magnetic field I find there is no doubt the particles composing the midway band consist of particles of mass 4 and charge 1, *i.e.* to singly charged helium atoms which have the same speed as the doubly charged particles comprising the main band.

Some recent experiments have been made by me to throw light on the conditions under which the flying α-particles may gain or lose an electron. The general arrangement of the experiment is shown in Fig. 1. A fine platinum wire coated with radium B+C, by exposure to the emanation (radon) serves as a nearly homogeneous source of α-rays, since the α-particles are emitted only from the atoms of radium C, which are too few in number to form a film on the platinum of even one molecule thick. The α-rays from this source pass through a narrow slit about 0·3 mm. wide and fall on a screen of zinc sulphide. The distribution of α-particles on the screen is determined by the scintillation method in a dark room, using a microscope outside the box. The vessel containing the source and screen is completely exhausted by means of a Gaede and mercury diffusion pump, and if necessary the residual pressure can be measured by a Macleod gauge. The box is placed between the plane pole pieces of a large electromagnet so that the pencil of α-rays is bent in the direction shown in the figure. Usually the distance between the source and screen was 16 cm., with the slit midway. The whole path of the rays was exposed to a nearly uniform magnetic field and the deflexion of the pencil of rays was proportional to the strength of the magnetic field. Under normal experimental conditions the pencil of α-rays from the

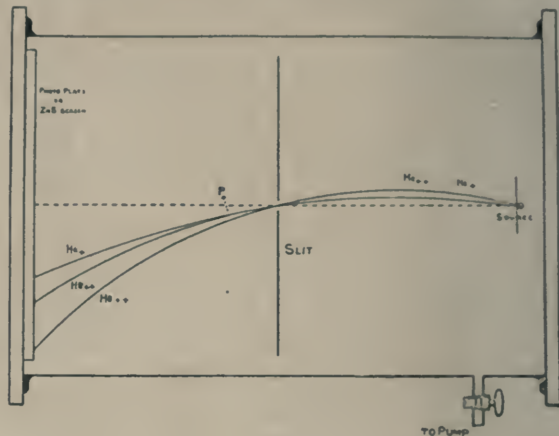

FIG. 1.

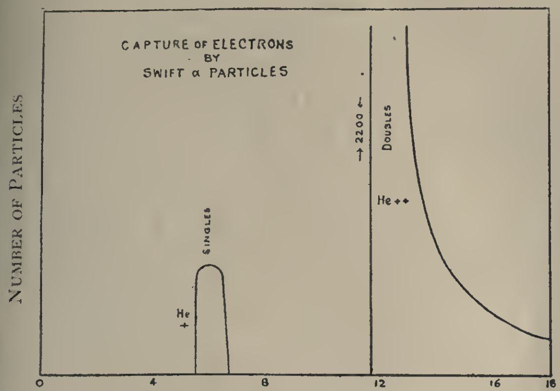
bare radium C wire was bent a distance on the screen of about 15 mm. from the zero position without field. The field of view of the microscope was sufficient to take in the depth of the whole pencil of α-rays without the field.

Special precautions were taken to prevent contamination of the screen by the escape of active matter from the wire in a low vacuum. It must be borne in mind that the type of wire source employed always introduces some heterogeneity in the beam of α-rays even from the uncovered source. This is due to the escape from the back of the wire of α-particles which are reduced in velocity in passing through the material. This effect is clearly manifest when the pencil of α-rays is deflected by a magnetic field; for in addition to the main band of α-rays there is always a distribution of particles extending beyond the main beam. The intensity of this heterogeneous beam at any point is generally less than one per cent. of the main beam and does not seriously interfere with the accuracy of the deductions discussed in this lecture.

In Figs. 2 and 3 are given illustrations of the distribution of singly and doubly charged α-particles

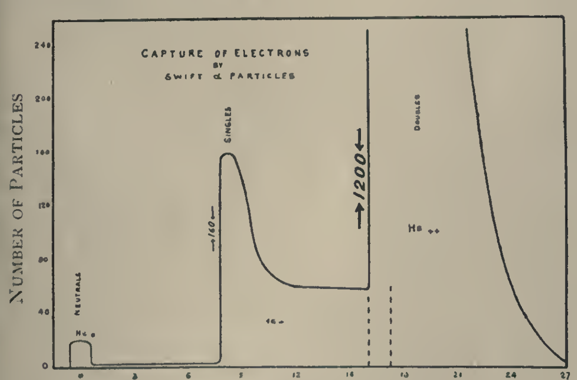
along the zinc sulphide screen. Fig. 2 shows the result when a thickness of mica corresponding in stopping power to 3·5 cm. of air is placed over the source. The main band, due to He_{++} particles, is sharply defined on the high velocity side, but there is evidence of some heterogeneity produced in the beam by its passage through the mica. As we should expect, the midway



DEFLEXION IN MM. BY MAGNETIC FIELD

FIG. 2.

band (He_{+} particles) lies exactly between the zero position and the main band and contains only about 1/55 of the particles in the main beam. Fig. 3 shows the distribution when the thickness of mica is increased to correspond to a stopping power of about 6 cm. of air. Both the main and midway bands are no longer sharply defined as in the first case, but each

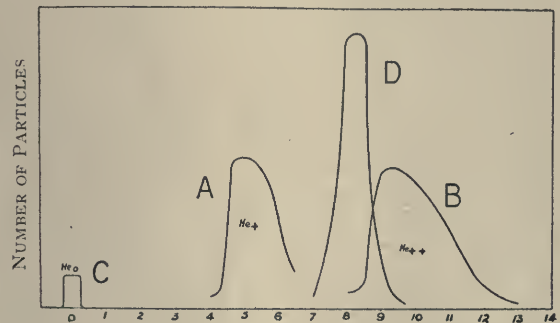


DEFLEXION IN MM. BY MAGNETIC FIELD

FIG. 3.

consists of particles with a considerable range of velocities. The relative number of He_{+} and He_{++} particles is about 1/8 for the swifter particles, but this ratio increases with decreasing velocity. The midway band extends and joins the main band where it can no longer be followed. The brightness of the scintillations due to He_{+} particles falls off obviously and continuously from A to B. At this stage, too, some neutral particles make their appearance. This is shown by the He_0 band, which is not deflected by a magnetic field, but its intensity is small compared with that of the midway band. There is also a sparse distribution of faint particles between the neutral and midway band, probably due in part to scattering of the α-particles by the edges of the slit and possibly in part due to recoil atoms of oxygen and other elements constituting the mica. The distribution of the charged and uncharged helium particles for a still lower velocity will be seen in curves A, B, Fig. 4, which will be referred to later. It is seen that the relative number of He_{+} to He_{++} particles has increased; similarly, the relative number of neutral particles is much greater.

We may now consider the interpretation to be placed on these observations. It is clear that the particles emerging from the mica consist of doubly charged, singly charged, and neutral particles, but the relative number of these three types varies markedly with the stopping power of the mica plate. We may suppose that the α-particle in passing through the outer electron



DEFLEXION IN MM. BY MAGNETIC FIELD

FIG. 4.

structure of the atoms in its path occasionally removes and captures an electron. This electron falls into a stable orbit round the doubly charged helium nucleus and moves with it.

This singly charged atom will, however, have only a limited life, for in passing through other atoms the electron is knocked off and the singly charged α-particle reverts back to the doubly charged type. This process of removal is analogous to the ordinary process of ionisation where an electron is ejected from an atom by a collision with an α-particle; for as a singly charged particle can remove electrons from another atom, so there is a chance that the He_{+} particle should lose its attendant electron. We may thus consider that two opposing processes are at work, one resulting in the capture of an electron and the other leading to its removal. From the data given later it will be seen that this process of capture and loss may repeat itself more than a thousand times in the flight of an α-particle, so that the average path travelled by an α-particle before capture of an electron or before loss of the captured electron is small compared with the total

distance of travel of the α-particle before it comes to rest. It is clear from this, for a given velocity of α-particle, that there must be a momentary equilibrium between the number of He_+ and He_{++} particles such that, on the average, the number of captures in a given small distance is equal to the number of losses.

It is very convenient to suppose that for a given velocity each He_{++} particle has a mean free path λ_1 cm. in the material before it captures an electron, and the He_+ particle a mean free path λ_2 cm. before it loses its attendant electron. No doubt some of the individual particles travel distances much shorter or longer than this mean distance before either capture or loss, but in considering a large number of particles we may suppose there is an average distance traversed before capture or loss, to be called the mean free path.

When N_1 He_{++} particles traverse a small distance dx of a material the number which capture electrons is $N_1 dx/\lambda_1$. If N_2 He_+ particles are present the number which lose an electron is $N_2 dx/\lambda_2$. But we have seen that when an equilibrium is set up, the number of captures in a given distance must equal the number of losses. Equating these two expressions, it is seen that $N_2/N_1 = \lambda_2/\lambda_1$, or, in other words, the relative number of He_+ to He_{++} particles is proportional to the ratio of the mean free path for loss to that for capture. Since by the scintillation method the ratio N_2/N_1 can be measured for any velocity, by using different thicknesses of absorber we can thus determine the ratio of the mean free paths for capture and loss for any velocity.

The actual value of the mean free path λ_2 of the He_+ particle before it loses its electron can be directly determined by experiment. Suppose the microscope is focussed on the midway band of Fig. 2 and the number of scintillations per minute observed in a good vacuum. If the pumps are shut off and a small quantity of air or other gas is introduced into the apparatus, the number of scintillations is found to diminish with increasing pressure of the air until the band has completely disappeared. This takes place at quite a low pressure of air, for example, for a pressure of about 1/4 mm. in the box.

The explanation of this result is obvious. The He_+ particles which escape from the mica occasionally collide with an atom of the gas in its path, and the electron which it captured in passing through the mica is removed. In such a case the He_+ becomes again an He_{++} particle, and the latter is twice as easily deflected in a magnetic field as the former. Suppose the collision occurs for the first time at the point P (Fig. 1). The particle after losing its electron travels along a new path shown in the figure, and the particle no longer strikes the part of the screen viewed by the microscope. It is found that the number of scintillations seen in the microscope falls off according to an exponential law as the pressure of the gas is raised. Such a result is to be expected, and from this data the average distance which the He_+ particle traverses before it loses its electron can be simply deduced. Certain small corrections are necessary to take into account the finite width of the band of scintillations as seen in the microscope, but we need not enter into details at this stage. It is convenient to express the mean free path λ_2 in air of the He_+ particles, not as the average length of path traversed in the rarefied gas before loss, but as the distance traversed in the same gas at standard pressure and temperature. For example, in a certain experiment, the mean free path in air of the particle was found to be 12 cm. at a pressure of 0·040 mm.; this corresponds to a mean free path of 0·0063 mm. at standard pressure and temperature.

In this way the mean free path in air before loss of an electron has been measured for different velocities, and it has been found over a considerable range that the mean free path varies directly as the velocity of the α-particle, so that the mean free path becomes shorter as the velocity of the α-particle diminishes. Since we may regard the loss of an electron from the singly charged particle as the result of a process of ionisation, such a relation is to be expected, and indeed, if we take into account the strong binding of a single electron by the He_{++} nucleus, the mean free path for loss is of the same order as that calculated from considerations of the number of ions per cm. produced by the α-particle in air and other gases. Comparisons have been made of the mean free path in air with that in hydrogen and helium. Its value is 4 to 5 times longer in hydrogen and more than 5 times longer in helium.

Now that the mean free path λ_2 is known, the value of λ_1 for capture can be deduced if the ratio N_2/N_1 is also known. A difficulty, however, arises at this point. In order to measure the ratio N_2/N_1 it is necessary that the active source should be covered with mica or other solid material. Gas cannot be used conveniently. It was found, however, that the ratio N_2/N_1 was the same within the limits of error whether the α-particles were reduced in velocity by passage through celluloid, mica, aluminium, or silver. For this purpose the mica was kept the same and a very thin sheet of the substance under examination spread over it. The thickness of the sheet was sufficient to set up a new equilibrium between the singly and doubly charged particles, but not sufficient to alter materially the velocity of the ionising rays.

Since the value of the ratio N_2/N_1 suffers no appreciable change for absorbers of such different atomic weights, we may safely conclude that the ratio for a

hypothetical sheet of solid air would be the same as for mica.

We have now all the data required to determine the values of λ_1 and λ_2 corresponding to α-particles of different velocities. The results are given in the following table for three different velocities. The mean free paths are expressed in terms of millimetres of air at standard pressure and temperature. V_0, the maximum velocity of the α-particles from radium C, is $1{\cdot}9 \times 10^9$ cm. per second.

Velocity V in terms of V_0.	$\lambda_2/\lambda_1 = N_2/N_1$ for Mica.	Mean Free Path λ_2 for Loss in Air.	Mean Free Path λ_1 for Capture in Air.
0·94	1/200	0·011 mm.	2·2 mm.
0·76	1/67	0·0078 mm.	0·52 mm.
0·47	1/7·5	0·0050 mm.	0·037 mm.

It has been seen that the mean free path for loss varies directly as the velocity, and thus only alters in a ratio of about 1 to 2 over the range of velocities given in the table. On the other hand, the ratio λ_2/λ_1 increases very rapidly with diminution of velocity varying approximately as V^{-5}. From this it follows that λ_1 varies as V^6, thus decreasing by a factor of 60 or more when the velocity is halved.

From these data and relations it can easily be calculated that the mean free path for capture should be equal to that for loss for a velocity about $0{\cdot}3\ V_0$, and for this speed the numbers of He_+ and He_{++} particles should be equal.

The actual value of the velocity for equality of the two types in a special experiment was found to be $0{\cdot}29\ V_0$, in good agreement with the calculated value. It is a difficult matter to determine the values of λ_1 and λ_2 for velocities less than $0{\cdot}3\ V_0$, for not only are the scintillations weak in intensity and difficult to count with accuracy, but also the issuing rays are very heterogeneous and no longer show well-defined edges on the high velocity side. It was, however, noted that the ratio N_2/N_1 rapidly increased below the velocity $0{\cdot}3\ V_0$.

We have so far dealt with the equilibrium between He_+ and He_{++} particles. It is clear, however, that similar considerations apply to the equilibrium between singly charged and neutral helium particles at low velocities of the α-particle. It was noted that the neutral particles appear prominently after the rays have passed through mica of 6 cm. stopping power, but no doubt they could be detected for still lower stopping power. These neutral particles, of course, produce scintillations, but of an intensity corresponding to an α-particle of low velocity. These neutral particles probably lose and regain an electron many times before they are stopped in the zinc sulphide or other absorbing material. This effect was shown by introducing gas at low pressure into the apparatus, when the scintillations due to the neutral particles diminished in number and ultimately vanished. The explanation of this is similar to that given for the disappearance of the He_+ band, for the neutral particles occasionally lose an electron in passing through the gas and are then deflected away from the zero position by the magnetic field.

It was estimated that the mean free path in air for conversion of neutral helium particles to singly charged particles was about 1/600 mm. No doubt this is an average for particles of very different velocities which may be present in the neutral band.

For the higher velocities we have to deal mainly with the interchange $He_{++} \rightleftarrows He_+$. For velocities less than $0{\cdot}5\ V_0$ the interchange $He_+ \rightleftarrows He_0$ also comes in and becomes all-important for velocities less than $0{\cdot}3\ V_0$. No doubt, as Henderson has shown, at still lower velocities most of the He_{++} particles disappear and the He_0 and He_+ particles predominate.

At these low velocities, counting scintillations becomes very difficult and uncertain, and the photographic method, as used by Henderson, is preferable. It will be a matter of very great interest to examine whether the relative numbers of the three types of particles alter when the α-particles are slowed down by passage through different materials. This side of the work is being attacked by Mr. Henderson in the University of Saskatchewan.

There is one very interesting point that may be considered here. It has been shown that these singly and doubly charged α-particles are always present after the α-rays have passed through mica or other absorber, but are there any singly charged particles present when α-particles escape from a wire coated with an infinitely thin deposit of active matter? This was first tested for a platinum wire coated with a deposit of radium B+C, by exposure to the radium emanation, when it was found that singly charged helium atoms were present in about the equilibrium ratio for this velocity. This was a rather surprising observation, but it was thought it might result from the fact that by the recoil from radium A the radium B particles penetrate some distance into the material of the wire. Under these conditions many of the α-particles expelled from radium C have to pass through a small but appreciable thickness of matter before escape from the wire and might thus capture electrons. This explanation seemed unlikely because the average distance penetrated by the recoil atom is only a minute fraction of the mean free path for capture at such high velocities of the α-particle. The experiment was tried with a nickel wire on which radium C had been deposited on

the surface by the well-known method of dipping the wire in a hot solution of radium C. In this case the difficulty due to recoil is absent, but the number of singly charged particles was the same as before.

It is very significant that the relative number of singly and doubly charged particles is about the equilibrium ratio to be expected when the wire, after being activated, is coated with an appreciable thickness of copper or other material. We can scarcely suppose that singly as well as doubly charged particles are actually liberated from the radioactive nucleus itself, for even if it be supposed that an α-particle with an attendant electron is expelled, the electron must be removed in escaping through the very powerful electric field close to the nucleus. It is much more probable that the doubly charged α-particle in passing through the dense distribution of electrons surrounding the radioactive nucleus occasionally captures an electron, and that the process of capture and loss goes on to some extent in escaping from the radioactive atom. This seems at first sight rather unlikely when we consider the relatively large number of atoms an α-particle ordinarily passes through before equilibrium between capture and loss is established, but it is well known that the chance of effective electronic collisions appears in general to be greater for a charged particle expelled from the central nucleus than for a similar particle passing from outside through the electronic distribution of an atom. It may be that those electrons, the orbital motion of which round the nucleus is comparable with the speed of the α-particle, are particularly effective in causing capture or loss.

So far we have dealt mainly with the distribution in a magnetic field of the particles in a vacuum after their escape from a mica surface. Some very interesting points arise when the distribution is examined in the presence of sufficient gas to cause a rapid interchange of capture and loss along the path of the α-particle in the gas. This is best illustrated by a diagram, Fig. 4, in which the results are given for α-particles escaping through mica with a maximum emergent range of about 4 or 5 millimetres in air. Curves A and B give approximately to scale the distribution of He_+ and He_{++} particles in a vacuum, while C gives the relative number of neutral particles under the experimental conditions. Suppose now sufficient air is introduced into the vessel to cause many captures along the gas but yet not enough to reduce seriously the velocity of the α-particles. The first salient fact to notice is that the distributions A, B, C vanish and there remains a distribution of particles (curve D) about midway between A and B. This band is narrower than either A or C, and its height at the maximum much greater than either. It is evident that the particles have been compressed into a band of much narrower width than the normal distribution in curve B.

This is exactly what we should expect to happen. The swifter particles present suffer less capture than the slow; consequently the average charge of the swifter α-particles along the gas is less than $2e$, and their deflexion is less than the swiftest particles shown in curve B. On the other hand, the slower α-particles have an average charge nearer $1e$ than $2e$ and are relatively still less deflected than the swifter particles. It is thus clear that the resulting distribution of particles with air inside the vessel will be concentrated over a much narrower width than the main band of He_{++} particles. From calculation based on the laws of capture and loss, the width of the band under the experimental conditions can be deduced and is found to be in good accord with experiment. It will be seen to be significant that similar results have been observed for hydrogen under corresponding conditions.

General Discussion of Results.

Attention may now be devoted to a consideration of the results so far obtained and the possibility of their explanation on present views. In the first place, it is important to emphasise the large number of capture and losses that occur during the flight of an α-particle from radium C. While the mean free path of the α-particle from radium C of 7 cm. range is about 3 mm. in air, its value rapidly decreases with lowering of the velocity of the α-particle and is probably about 0·0015 mm. for a velocity of 0·3 V_0. It is not difficult to calculate that not far short of a thousand interchanges of charge occur during the path in air of a single particle between velocities V_0 and 0·3 V_0. While the data so far obtained do not allow us to calculate the number of interchanges of charge that occur between velocities 0·3 V_0 and 0, it seems probable that the number is considerably greater than a thousand. We have already pointed out that for low velocities the interchange $He_+ \rightleftarrows He_0$ predominates. When we consider the rapidity of interchange of charges of the α-particle at average velocities, it seems clear that we cannot expect to observe any appreciable difference in power of penetration between a beam of rays of the same velocity, whether consisting initially of singly or doubly charged particles. It is clear that a singly charged particle after penetrating a short distance is converted into a doubly charged particle and *vice versa*, and that the effects due to the two beams should be indistinguishable. Henderson tried such absorption experiments, using the photographic method, but with indefinite results.

When an α-particle captures an electron, the latter presumably falls into the same orbit round the helium nucleus as that which characterises an ionised helium atom, *i.e.* an atom which has lost one electron. When the α-particle with its attendant electron passes swiftly through the atoms of the gas in its path, it will not only ionise the gas but will also occasionally be itself ionised, *i.e.* will lose its attendant electron. When we take into account the strong binding of the first electron to the helium nucleus—ionisation potential about 54 volts—the mean free path for loss of the captured electrons in air is of the right order of magnitude to be expected from considerations based on the ionisation by the α-particle per unit path in air. While we can thus offer a quantitative explanation of the mean free path for loss observed experimentally, the inverse problem of the capture of an electron by the flying α-particle presents very great difficulties.

In the actual case, the α-particle is shot at high speed through gas molecules which for all practical purposes may be supposed to be at rest. For convenience of discussion, however, it is preferable to make an equivalent assumption, namely, that the α-particle is at rest and

the gas molecules stream by it with a velocity equal and opposite to that of the α-particle. Now the maximum velocity of an α-particle from radium C is equivalent to that gained by an electron in falling freely between a difference of potential of about 1000 volts; so that the electrons comprising the molecules of air or other gas have a velocity of translation numerically equal to this. For brevity, it is very convenient to speak of this velocity or energy as that due to a "1000-volt" electron.

When the electrons in an atom pass close to the α-particle, one of them may be removed from the parent atom by the collision, energy being required for this process. The ionisation potential for oxygen or nitrogen is about 17 volts, which is a very small quantity compared with the energy of translation of a 1000-volt electron.

If we consider the forces involved between an α-particle and moving electron as of the ordinary electrostatic type, the electron will describe a hyperbolic orbit round the nucleus, the angle of deflexion of the path of the electron resulting from the collision depending on the nearness of approach of the electron to the nucleus. On ordinary dynamics, the electron will never be captured in such a collision if there is no loss of energy by radiation. If capture for some reason results from the collision, it means that an amount of energy corresponding to at least a 1000-volt electron has in some way been got rid of. This loss of energy may be supposed to be due to some interaction between the α-particle and colliding nucleus with its attendant electrons, or to the loss of energy by radiation during the collision. The first supposition seems at first sight plausible, for we know that the innermost electrons of oxygen or nitrogen are strongly bound and require energy of the order of 500 volts to remove them from the atom. But there is one very strong and, it seems to me, insuperable objection to this view.

I have found that the deflexion in a magnetic field of a pencil of α-particles passing through a suitable pressure of hydrogen is similar to that shown in curve Fig. 4 for air. This shows that the α-particle passing through hydrogen captures electrons of energy about 120 volts to about the same degree as in air. Now we know that the electrons in the hydrogen atom or molecule are lightly bound, and an energy of not more than a 30-volt electron, suitably applied, would entirely separate the component nuclei and electrons in the hydrogen molecule. In the case of hydrogen, therefore, we cannot hope to account for the requisite loss of energy, which for the experiment considered is about 100 volts. If these experiments with hydrogen are correct, and are valid for all velocities of the α-particle, we are driven to conclude either, that some unknown factors are involved in the capture, or that the loss of energy of the electron must be ascribed to radiation. In such a case, capture of an electron may be regarded as the converse of the photo-electric effect, where radiation falls on matter and swift electrons are ejected from the matter. In the case under consideration, swift electrons are shot towards a charged nucleus and an occasional electron is captured with the emission of energy in the form of radiation. On such an hypothesis the radiation of energy from an α-particle passing through a gas due to the frequency of capture is very great, amounting to about 3 per cent. of the total energy of the α-particle. This seems to be an unexpectedly large amount, but cannot be ruled out as impossible in the present state of our knowledge.

In the discussion of this very thorny question, I have confined myself mainly to the case of capture by the swift α-particle, where the difficulties of explanation are much greater than for capture at slower velocities. Our information is at present too incomplete to give a decisive answer, but there seems to be no doubt that the unexpected frequency of capture of electrons by swift α-particles raises many new and interesting questions of the nature of the processes that can occur in collisions between electrons and matter.

I need scarcely say that the phenomena of capture and loss are not confined to the α-particle, but are shown by all charged atoms in swift motion through a gas, and were long ago observed in the case of positive rays. On account, however, of the high velocity of the α-particles and the ease of their individual detection, the process of capture and loss can be studied quantitatively under simpler and more definite conditions than in the case of the electric discharge through a gas at low pressure.

On this occasion I have devoted my attention to the most recent additions to our knowledge of the life history of the α-particle. This knowledge has been obtained from the study of the rapid interchange of charges when an α-particle passes through matter. I have only incidentally referred to the numerous collisions with electrons along the track of the α-particle which result in dense ionisation. I have omitted any consideration of those rare but interesting encounters in which an α-particle is deflected through a large angle by a close collision with a nucleus. I have omitted, too, the still rarer encounters which may result in a disintegration of an atomic nucleus like that of nitrogen or of aluminium. We have seen that an α-particle has an interesting history. Usually it is retained as an integral and orderly part of a radioactive nucleus for an interval of more than a thousand million years. Then follows a cataclysm in the radioactive nucleus; the α-particle gains its freedom and lives an independent life of about one hundred millionth of a second, during which all the incidents referred to in this lecture occur.

If we are dealing with a dense and compact uranium or thorium mineral, the α-particle after acquiring two electrons and becoming a neutral helium atom may be imprisoned in the mineral as long as the mineral exists. The occluded helium can be released from the mineral by the action of high temperature, and after removal of all other gases can be made to show its presence by the characteristic brilliant luminosity under the stimulus of the electric discharge. In the circumstances of such an experiment, only small quantities of helium are liberated. Large quantities of helium, sufficient to fill a large airship, have, however, been isolated from the natural gases which escape so freely from the earth in various parts of Canada and the United States. It is a striking fact that every single atom of this material has in all probability had the life history here described.

Addendum.[1]

It may be of interest to give here a brief review of some additional facts in connexion with the α-particle, brought to light in recent years. It has long been known that α-particles, although projected from the source at the same speed, travel unequal distances through a gas. For example, the maximum distance travelled by the α-particles from radium C in air is 7·04 cm. at 760 mm. and 15° C., the minimum distance is about 6·4 cm., and the mean distance about 6·8 cm. Some "straggling" of the α-particles is to be anticipated on general grounds, since the α-particle loses its energy mainly in liberating electrons from the atoms of matter in its path. On the laws of probability, one α-particle may meet more atoms and liberate more electrons than another, and thus lose energy at a faster rate. The amount of straggling observed is, however, much greater than can be accounted for in this way, and the occasional large deflexions of the α-particles due to nuclear collisions are so rare, except near the end of the range, that they do not seriously influence the final distribution.

Henderson has suggested that the property of an α-particle of capturing and losing electrons will introduce a new factor in causing straggling. No doubt this is the case, but the rates of capture and loss observed appear to be too rapid to account entirely for the discrepancy between theory and experiment. Another interesting suggestion has been made by Kapitza to account for the magnitude of this straggling. From the experiments of Chadwick and Bieler on the collision between α-particles and hydrogen nuclei, it has been deduced that the α-particle or helium nucleus has an asymmetrical field of force around it. This asymmetry of the electric field must become small at the distance of the orbits of the electrons in the neutral helium atom, but may be sufficient to fix the plane of the orbit of an electron relative to the axis of the helium nucleus.

Suppose that the α-particles liberated from a radioactive source have their axis orientated at random, and that the direction of the axis of each individual particle remains unchanged during its motion. In some cases, for example, the captured electron will describe an orbit of which the plane is nearly in the direction of motion of the α-particle; in other cases nearly perpendicular to it. It is to be expected, however, that the chance of losing the captured electron by collision will be greater in one case than the other; or, in other words, the mean free path of the singly charged α-particle before loss of its electron will be different in the two cases.

On this view, it is to be anticipated that one group of α-particles will lose energy faster than the other, and the ranges will be different. In order to test whether α-particles show the individual differences to be expected on this theory, Kapitza has photographed in the Cavendish Laboratory the tracks of a number of α-particles by the Wilson expansion method, using a strong magnetic field of about 70,000 Gauss, produced by a momentary current of great intensity. The magnetic field was sufficiently strong to cause a marked bending of the track of the α-particle. It was found that the curvature of the tracks at equal distances from the ends showed marked variations. Before any definite decision can be reached, a large number of tracks obtained in this way must be carefully measured up and allowance made for the sudden bends which occur due to a nuclear collision with the atoms of nitrogen or oxygen. The frequency of these bends near the end of the range complicates the interpretation of the apparent curvature which is measured. The experiments, which are still in progress, are difficult and require great technical skill, and it will be a matter of much interest if any definite asymmetry in the orbits of the singly charged α-particles can be established by this or other methods. If such an asymmetry exists, it must influence to a small extent the arrangement of the two electrons round the helium nucleus and possibly their spectrum.

During the past two years, Blackett, in the Cavendish Laboratory, has made a careful examination of the frequency of occurrence of sharp bends or forks in the tracks of α-particles near the end of their range in air and other gases. For this purpose, a simple form of Wilson expansion chamber, of the type designed by Shimizu, has been used, and each track has been photographed in two directions at right angles to each other to fix the angle of the forks in space. A large number of photographs have been taken, and the frequency of the forks has been examined in different gases, particularly in the last centimetre of the range of the α-particle. Assuming that these forks arise from nuclear collisions, it is possible to deduce from the experimental data the variation of velocity of the α-particle near the end of its range. It is known from the work of Geiger and Marsden that the maximum velocity v of the α-particles of emergent range R is given by $v^3 \propto R$, when R is not less than one centimetre. Blackett finds that this relation between velocity and range no longer holds near the end of the track but is replaced by a relation of the form $v^{1\cdot5} \propto R$.

In the course of these experiments a number of well-defined forks have been photographed in hydrogen, helium, air, and argon by Blackett, and also by Auger and Perrin in Paris. By measuring the angles between the original direction of the α-particle and the direction of the colliding particles after collision, the accuracy of the laws of impact can be directly tested. The results are found, within experimental error, to be in agreement with the view that the impacts are perfectly elastic and that the conservation of energy and of momentum hold in these nuclear collisions. Conversely, by assuming that the impacts are perfectly elastic, it is possible to deduce the mass of the recoil atom in terms of the α-particle of mass 4·00. For example, a fork in helium gave the mass of the recoil atom 4·03, and a fork in hydrogen gave the mass of the recoil atom 1·024. In a collision between the α-particle and a helium nucleus the angle between the forks should be exactly a right angle; the value measured was 89° 45′.

[1] This did not form part of the Royal Institution discourse, but it may usefully supplement one or two of the points surveyed in that lecture.

The Revolt against the Teaching of Evolution in the United States.

THE movement in some of the Southern and Western United States to suppress the teaching of evolution in schools and universities is an interesting and somewhat disconcerting phenomenon. As it was I who, all unwittingly, dropped the spark which started the fire, I welcome the invitation of the Editor of NATURE to comment on the consequences.

First as to my personal share in the matter. At the Toronto meeting of the American Association I was addressing a scientific gathering, mainly professional. The opportunity was unique inasmuch as the audience included most of the American geneticists, a body several hundreds strong, who have advanced that science with such extraordinary success. I therefore took occasion to emphasise the fact that though no one doubts the truth of evolution, we have as yet no satisfactory account of that particular part of the theory which is concerned with the origin of *species* in the strict sense. The purpose of my address was to urge my colleagues to bear this part of the problem constantly in mind, for to them the best chances of a solution are likely to occur. This theme was of course highly academic and technical. Nevertheless, to guard against misrepresentation, I added the following paragraph by the advice of a friend whose judgment proved sound, though to me such an addition looked superfluous.

"I have put before you very frankly the considerations which have made us agnostic as to the actual mode and processes of evolution. When such confessions are made the enemies of science see their chance. If we cannot declare here and now how species arose, they will obligingly offer us the solutions with which obscurantism is satisfied. Let us then proclaim in precise and unmistakable language that our faith in evolution is unshaken. Every available line of argument converges on this inevitable conclusion. The obscurantist has nothing to suggest which is worth a moment's attention. The difficulties which weigh upon the professional biologist need not trouble the layman. Our doubts are not as to the reality or truth of evolution, but as to the origin of *species*, a technical, almost domestic, problem. Any day that mystery may be solved. The discoveries of the last twenty-five years enable us for the first time to discuss these questions intelligently and on a basis of fact. That synthesis will follow on analysis, we do not and cannot doubt."

The season must have been a dull one, for upon this rather cold scent the more noisy newspapers went off full cry, with scare-headings "Darwin Downed," and the like.

All this seemed foolish enough, and that practical consequences would follow was not to be expected. Nevertheless, Mr. William Jennings Bryan, with a profound knowledge of the electoral heart, saw that something could be made of it and introduced the topic into his campaign, which, though so far harmless in the great cities, has worked on the minds of simpler communities. In Kentucky a bill for suppressing all evolutionary teaching passed the House of Representatives, and was only rejected, I believe, by one vote, in the Senate of that State. In Arkansas the lower house passed a bill to the same effect almost without opposition, but the Senate threw it out. Oklahoma followed a similar course. In Florida, the House of Representatives has passed, by a two-thirds vote, a resolution forbidding any instructor "to teach or permit to be taught Atheism, agnosticism, Darwinism, or any other hypothesis that links man in blood relation to any form of life." This resolution was lately expected to pass the Senate. A melancholy case has been brought to my notice of a teacher in New Mexico who has been actually dismissed from his appointment for teaching evolution. This is said to have been done at the instigation of a revivalist who visited the district, selling Mr. Bryan's book.

The chief interest of these proceedings lies in the indications they give of what is to be expected from a genuine democracy which has thrown off authority and has begun to judge for itself on questions beyond its mental range. Those who have the capacity, let alone the knowledge and the leisure, to form independent judgments on such subjects have never been more than a mere fraction of any population. We have been passing through a period in which, for reasons not altogether clear, this numerically insignificant fraction has been able to impose its authority on the primitive crowds by whom it is surrounded. There are signs that we may be soon about to see the consequences of the recognition of "equal rights," in a public recrudescence of earlier views. In Great Britain, for example, we may witness before long the results which overtake a democracy unable to tolerate the Vaccination Act, and protecting only some 38 per cent of its children.

As men of science we are happily not concerned to consider whether a return to Nature, as a policy, will make for collective happiness or not. Nor is it, perhaps, of prime importance that the people of Kentucky or even of "Main Street" should be rightly instructed in evolutionary philosophy. Mr. Bryan may have been quite right in telling them that it was better to know "Rock of Ages" than the ages of rocks. If we are allowed to gratify our abnormal instincts in the search for natural truth, we must be content, and we may be thankful if we are not all hanged like the Clerk of Chatham, with our ink-horns about our necks.

For the present we in Europe are fairly safe. A brief outbreak on the part of ecclesiastical authority did follow the publication of the "Origin of Species," but that is now perceived to have been a mistake. The convictions of the masses may be trusted to remain in essentials what they have always been; and I suppose that if science were to declare to-morrow that man descends from slugs or from centipedes, no episcopal lawn would be ruffled here. Unfortunately the American incidents suggest that our destinies may not much longer remain in the hands of that exalted tribunal, and that trouble may not be so far off as we have supposed.

W. BATESON.

The Unity of Anthropology.

Die Kultur der Gegenwart: ihre Entwicklung und ihre Ziele. Herausgegeben von Paul Hinneberg. Dritter Teil: Mathematik, Naturwissenschaften, Medizin. Fünfte Abteilung: Anthropologie. Unter Leitung von G. Schwalbe und E. Fischer. Pp. viii + 684 + 29 Tafeln. (Leipzig und Berlin: B. G. Teubner, 1923). *22s. 7d.*; cloth, *27s. 4d.*

ANTHROPOLOGY, the science of man—a proud name indeed! But, alas, there is little at present but the name which stands for the unity of this science. Its subject matter it has to share with anatomy, biology, theories of heredity and variation, geology, sociology, and social psychology. Its methods are borrowed from several natural and humanistic sciences. Its aim and scope seem at first but arbitrarily claimed and loosely circumscribed by man's excessive conceit about his own importance as a central object of study. After all, man is physically but one animal species among others, while his soul has been for a long time already in the keeping of another science—that of psychology.

The unfortunate fact is that man has been created with a body and a soul as well, and this original sin, after having incessantly haunted the reflective mind through myth, religion, theology, and metaphysics, comes now to lay its curse on anthropology. Physical and cultural anthropology are divided by the deep rent between soul and body, matter and mind, which is no easier to bridge over in science than in the somewhat looser speculations which precede it.

An anthropologist has to be a Jack-of-all-trades as matters now are, however much he may deplore it, and he needs a good handbook of his science, wherein to store that part of his stock in trade which is not kept fresh by constant handling in his own specialist's

workshop. Until the appearance of the present volume there was no satisfactory manual covering the whole field, or rather the several plots embraced by the name Anthropology. In a science where real unity is impossible, no one can specialise in all its branches. Collaboration is the only way of dealing with each subject in an adequate manner; and no better or more competent collaborators could be found than the six German savants whose names figure here on the title-page.

The handbook is the fifth part of the section devoted to natural science in the monumental series which is being published under the title "Die Kultur der Gegenwart" by B. G. Teubner, and aims at an exhaustive statement of the present state of knowledge. It commands real admiration to see how this extremely ambitious, yet thoroughly adequate, scheme is being carried out, in spite of the interruption caused by the War, in spite of the hard economic struggle which the academic classes in Germany have to face, in spite of the critical state of the publishing trade in that country.

There is first in this volume a short introductory chapter by Prof. E. Fischer, giving a systematic initiation into the subject, a clearing up and ordering of the field, so dear to the methodical mind of the German, and, to tell the truth, so extremely important and useful in a manual. In this case, the introduction is written with a strong somatological bias, and treats the cultural side of our science in a rather stepmotherly manner. The history of anthropology, for example, contains no reference to any of the great pioneers of cultural anthropology; the names of Bastian, Tylor, Frazer, Durkheim are not even mentioned. On the whole, it is the least satisfactory section of the book. There follow four parts exclusively devoted to physical anthropology: Part II., on Measurements, by Prof. Th. Mollison; Part III., Somatology, by Prof. E. Fischer and Th. Mollison; Part IV., the Human Races, by Prof. Fischer; Part V., the Theory of Human Descent, by the late Prof. G. Schwalbe. These parts are all one could wish for—clear, concise, up-to-date, exhaustive. The next part is an account of prehistoric anthropology by the late Prof. M. Hoernes. This part is naturally divided between the fields of physical and cultural anthropology. Only the last two of the eight essays belong entirely to the other—to the social, or cultural aspect of anthropology. Of these the one is an account of ethnology, by Dr. F. Graebner. The other, entitled "Sozialanthropologie," and written by Prof. A. Ploetz, is a very suggestive but as yet only tentative attempt at a correlation of race with cultural achievement, an attempt to construct a theory of the organising and civilising values of each of the several varieties of mankind.

Two of these essays will be of special interest, for they are not only the last word of science on the subject of pre-history and theory of descent, but they are also the last contribution of two very eminent scholars, Prof. Hoernes and Prof. Schwalbe, both of whom died while the book was in the publisher's hands.

On the whole, the volume will be of great use as a handbook specially to the social anthropologist—using this word in the English sense—just because the physical branches have been worked out at a greater length and in a more final and authoritative manner. Now naturally, if you are an anthropologist specialised in a corner of your field, you need to have the other plots well mapped out. In your own little plot you ought to find your way without a map!

Nor is it possible in the present state of cultural anthropology to give a final and entirely impartial statement of its results. For its methods, its aim, and its subject matter are in a flux, and there is very little agreement even on points of fundamental importance. As is well known, the value of the old evolutionary theories is being vigorously contested, while there is a great deal of dissension and confusion about the place of "psychological," "historical," and "sociological" explanations. Dr. Graebner is one of the pioneers of the "historical" school and its ablest exponent in Germany. This school concentrates its attention on the analysis of "cultural complexes," on the diffusion of institutions, customs, and cultural objects, and on the mechanism of culture-contact.

Many anthropologists in Great Britain will no doubt be interested in Dr. Graebner's essay—both those who wish to see perhaps the most exhaustive account of their own point of view extant, and those who wish to have a clear statement for criticism.

Dr. Graebner states his case in an introductory discussion of the aims of ethnology (pp. 445-447) and in a final summing up (pp. 572-583). The body of the essay contains first the analysis of the various cultures of humanity—savage, barbarous, and civilised. In the second main section there is an account of the evolution of the various elements of culture—clothing and ornaments, housing, economics, technology, trade and communication, social organisation, art and knowledge. This part is extremely interesting, for it shows very forcibly how fruitful and interesting evolutionary theories can be when based on a conception of humanity, divided into a number of cultural types and not lumped together into one homogeneous whole. Dr. Graebner's essay might go very far towards the clearing up of misunderstandings, convincing the intransigent opponents of the historical school, and, last though not least, towards the levelling up of the sharp rift which now divides the cultural and evolutionary schools in England, Germany, and the United States.

The essay, it seems, was practically finished before the War, and this explains why the work of Dr. Rivers finds only a subordinate place, while the still more radical and extremely interesting theories of Prof. Elliot Smith and Mr. Perry are not even mentioned. The work of Prof. A. R. Brown of Cape Town on the Andaman Islanders, easily the best contribution of the youngest generation of field anthropologists and very important in its bearing on the Negrito culture, came out too late to be considered. Had Dr. Graebner been able to incorporate the views of these scholars in his essay, this would have become of still greater value to modern ethnology.

Returning now to the question raised at the outset, that, namely, of the unity of anthropology, it is clear that this work reflects the present state of affairs as well as the prevalent tendencies : a deep rent between the physical and cultural branches ; a preponderance given to the physical ones ; and, within the cultural branches, an attitude of hostility to psychology and evolution.

On these lines, however, anthropology certainly will never attain its desired unity. For, first of all, so-called physical anthropology is not a new science or a new method or a new point of view. " We have to regard anthropology as nothing else but a comparative anatomy of man " (Prof. Schwalbe, p. 227). Nor is it easy to see how and where such comparative anatomy can establish any direct connexion with the study of human culture, or help in the understanding of social organisation, custom, and tradition. The only point where cultural anthropology needs the assistance of the naturalist is in the classification of the several varieties of mankind. Even here, comparative anatomy has already given us apparently all it could, which has been of great value indeed. But now, it is from biology, mainly from theories of natural selection, variation, and Mendelism, that we can hope for effective contributions to progress. Thus physical anthropology is not a new or independent science, but the application of several natural studies to the problem of varieties of man. Nor can physical anthropology ever be capable of throwing light on the relevance of these varieties. For a human race does not interest us as a mere class of animals, but only in so far as it is a substratum for a definite type of civilisation.

The study of civilisation—" cultural " or " social " or " psychological anthropology "—is the only science which can take the lead in the organising of anthropological problems, for it studies that which is of primary interest to us in Man : his mind, his creative power, and his social tradition. Cultural anthropology is, moreover, an entirely new branch of learning. Its field-work, the observations on the customs, social organisation, and mentality of natives, must be done by specialists possessing certain particular aptitudes as well as an appropriate training. The theory of cultural anthropology has also to elaborate its own methods, which it can borrow from nowhere else and share with no other study.

An empirical proof of this far wider scope of cultural as against physical anthropology can be found in the history of modern field-work and theory. Sir Baldwin Spencer, a distinguished zoologist who took up field-work late in life, was gradually drawn into exclusively social and cultural studies, and in his latter researches did not trouble about any measurements or somatological observations, while he concentrated exclusively on his remarkable researches into the ideas and institutions of the Australian aborigines. Dr. Rivers, a neurologist, physiologist, and medical man, who in his earlier field-work still made some anatomical and physiological observations, gave them up entirely, as irrelevant, in his latter explorations in Melanesia, in which he has created a new type of cultural research. In the work of Dr. Haddon and Prof. Seligman, again one a zoologist and the other a medical man, physical anthropology plays an entirely subordinate part, although neither of them has given up somatology altogether. Again in theory, we see how a distinguished anatomist, Professor Elliot Smith, who became interested in ethnology through anatomical observations, has been drawn, in his ethnological work, entirely into sociological, cultural, and psychological research.

Not that cultural anthropology should ever become independent of the naturalist's help or give up its foundations of zoological science. Only it appears that it will have to turn to the study of life and function rather than that of bones, muscles, and structure. The biometrical line of research, the work done by the Eugenic Society, the applications of Mendelism to anthropology seem all to be symptoms and promises of extremely interesting results to follow. It is undoubtedly a pity that some of the results already obtained by these studies could not be incorporated in this manual. They certainly indicate much more promising and important lines of junction between the theory of organic nature and that of culture than those on which was based the old loveless and sterile marriage between anatomical description and psychological guesswork. For the psychology which is needed in modern anthropology is no more the old associationist and introspective empiricism, but biological psychology founded on a comparative study of instinct and largely inspired by the study of animal behaviour, the child's development, mental disorders, the analysis of dreams and of the structure of language.

In all these applications, the guiding and selecting initiative must come from the direct study of culture. On these lines and on these lines only the new anthropology can hope to ripen in the future to an independent, self-contained, and sovereign study with a firm basis in biological science, itself a solid bridge between humanism and natural history. But this is only a hope and a forecast! Much work will have to be done yet, and in this, the present volume, an excellent summary of the actual state of our science will be of great help and value.

B. Malinowski.

Sexual Physiology.

The Physiology of Reproduction. By Dr. Francis H. A. Marshall. Second and revised edition. Pp. xvi + 770. (London: Longmans, Green and Co., 1922.) 36*s.* net.

With the gradual rise of the experimental school in biology, and with the increasing demand for scientific method in veterinary and medical practice, the existence of a definite gap in scientific literature came to be recognised. Nowhere was the subject of the physiology of reproduction dealt with at all adequately; in the ordinary text-book of physiology it was dismissed after a very superficial treatment. Moreover, there was not a physiologist competent to write upon this subject at all authoritatively. Biologists, pure and applied, owe a great debt of gratitude to Dr. Marshall for having chosen this field in which to work; for, thanks to his labours, the difficulties of a great band of research workers have been made much less complex.

The second edition of this comprehensive text-book on sexual physiology maintains the reputation so readily secured by its predecessor, published thirteen years ago and long since out of print. It is born into a world somewhat different from that in which the first edition played its part so well; the specialities have become so fragmented that to-day no one book on this subject can hope to satisfy the demands of such varied interests as those of the experimental biologist, the cytologist, the embryologist, the psychologist, the geneticist, the veterinarian, the obstetrician, and the eugenist. Each no doubt will discover disappointing omissions and conclude that his own particular interest has been somewhat neglected; yet it cannot be denied that the book remains the only common meeting-ground for all those who are working on the general subject of the physiology of reproduction. It is a most admirable book of reference for the specialist in one branch who wishes to examine his conclusions in the light of the work of others, while to the student of biology at the beginning of his career it will prove a veritable mine of information and a great stimulus to his scientific curiosity, for in its pages a hundred and one problems, all urgently demanding further investigation, are suggested. When it is remembered that Dr. Marshall reviews the work of some fourteen hundred investigators, that for the exposition of the subject-matter nearly eight hundred pages are required, and that for the making of the book the collaboration of four specialists was demanded, an idea of the immense amount of research that has been and is being done in this most important subject will be gained.

Dr. Marshall himself is responsible for the chapters dealing with the breeding season, the œstrous cycle, the œstrous changes in the non-pregnant uterus and in the ovary, gametogenesis, the accessory sexual apparatus, the endocrine function of the gonads, parturition, lactation, fertility, sex-determination, and the phases in the life of the individual. Dr. Cramer has revised and partly rewritten his section on the biochemistry of the sexual organs, and has also revised that originally contributed by Dr. Lochhead on the changes in the maternal organism during pregnancy. Dr. Lochhead's other sections on fœtal nutrition and on the physiology of the placenta, owing to the author's absence from Great Britain, unfortunately have not been revised.

The least satisfactory part of the book, both as regards arrangement and subject-matter, is, we think, that contributed by Dr. Cresswell Shearer on fertilisation. It begins with a section on the oxidation processes in the ovum on fertilisation and during development; it concludes with one on parthenogenesis, natural and artificial, in which the actual processes which initiate cleavage are discussed; while between the two we find, *inter alia*, under "The hereditary effects of fertilisation" a quite unnecessary statement of Weissmann's speculations grafted gratuitously on to an elementary exposition of Mendelism. In this the author, apparently through an inadequate comprehension of the chromosome hypothesis, devotes a considerable amount of space to tilting at windmills of his own creation without attempting to initiate the reader into the actual facts which have been demonstrated by Morgan and his school. Surely, if it was not the author's purpose to deal with experimental genetics, it would have been better to have omitted all reference to the subject than to have detailed a nomenclature which is of historical interest only and to have criticised hypotheses of which the significant data are not mentioned. But, as we have said, no specialist will find his own peculiar interest satisfactorily treated in this book: the obstetrician will complain that the phenomena connected with the function of reproduction in the human subject do not meet with the treatment that they deserve, the psychologist will perhaps disagree with

Dr. Marshall's choice of his authorities in this particular field, but each must remember that this book has been written not for one interest but for all that are concerned with the physiology of reproduction.

As it stands, the book is the best treatise on the subject that we have, and it is because it is so good and so valuable that its beneficiaries are so concerned in its further development. It must remain the best book on the subject and a memorable contribution to British scientific literature. F. A. E. C.

Applied Organic Chemistry and International Trade.

(1) *Synthetic Colouring Matters: Vat Colours.* By Prof. Jocelyn Field Thorpe and Dr. Christopher Kelk Ingold. (Monographs on Industrial Chemistry.) Pp. xvi+491. (London: Longmans, Green and Co., 1923.) 16*s*. net.

(2) *Dyes and their Application to Textile Fabrics.* By A. J. Hall. (Pitman's Common Commodities and Industries.) Pp. ix+118. (London: Sir Isaac Pitman and Sons, Ltd., n.d.) 3*s*. net.

(3) *Handbuch der biologischen Arbeitsmethoden.* Herausgegeben von Prof. Dr. Emil Abderhalden. Lieferung 84. Abt. I: *Chemische Methoden.* Teil 10, Heft 3: *Spezielle chemische Methoden. Harze und Pflanzenfarbstoffe.* Pp. 585-832+xxii. (Berlin und Wien: Urban und Schwarzenberg, 1922.) 10.5 Schw. francs.

DURING the period which has elapsed since the Armistice, events in the domain of international trade confirm the belief engendered by the War that the manufactures based on applications of organic chemistry are among the most important of our key industries. The pre-War dependence on German sources for the supply of fine chemicals was a national menace, which has since been largely obviated by the creation of a new industry in organic chemicals entirely unprecedented in the annals of the British Empire. A remarkable achievement standing to the credit of the manufacturers of synthetic dyes and intermediates may be appreciated by the circumstance that whereas in 1914 eighty per cent. of these colours used in Great Britain were of German origin and only twenty per cent. of home production, nowadays these proportions are reversed, British makers accounting for eighty per cent. of the total supply, the remainder coming from abroad, and at present more from Switzerland than from Germany.

In regard to certain complicated colours, such as the vat dyes, now being produced for the first time in Great Britain, it is generally admitted by dye users that the quality is well up to continental standards, but a difficulty arises in the matter of cost of production. Owing to the disparity between the exchanges this cost is far lower in Germany than in Great Britain. A vat dye put on the market by British makers at four or five shillings per pound can be sold with profit for the same number of pence by the German producers. It should be obvious that without the partial protection afforded by the Dyestuffs Act the British manufacturers must get the worst of this unfair competition. The closing down of our newly established works in dyes and intermediates would, however, mean "Never again" in a sense very different from that in which this patriotic exclamation was uttered in 1914. The value of a home supply of dyes has already been clearly demonstrated since the French and Belgian occupation of the Ruhr rendered very uncertain the importation of German colours even under licence.

(1) The monograph on vat colours by Prof. Thorpe and Dr. Ingold deals with an important group of dyes which are among the most durable and brilliant of colouring matters. This group includes not only the long-known dyes, indigo and Tyrian purple, but also several series of new colours discovered during the present century. These dyes have highly complicated chemical structures and are produced by difficult operations taxing to the utmost the skill and ingenuity of scientifically trained industrialists. It is noteworthy that vat dyes are now being manufactured by at least three British firms, and the chemists engaged in this industry have not only copied very successfully the German types, but also have placed on the market several entirely new and valuable vat colours. The monograph now under review, which arrives at a crucial time in the history of British chemical industry, is the first English treatise dealing with this intricate group of synthetic dyes.

(2) Mr. Hall's handbook, which is one of a series dealing with common commodities and industries, is written for the non-technical reader and is intended to give him a comprehensive view of the dye and dyeing industries. In an outline of the development of the dye industry it is significant to note the opening sentence of the first letter which ever passed between a dye user and a synthetic dye maker. Messrs. Pullar, writing to the discoverer of mauveine in 1856, stated, "If your discovery does not make the goods too expensive it is decidedly one of the most valuable that has come out for a very long time." This matter of cost is still a burning question between makers and users, and the presence in allied and neutral countries of parcels of dirt-cheap German dyes tends to make our dyers and printers chafe against the restrictions imposed under the Dyestuffs Act. But since the principal Rhenish dye factories are within the allied spheres of occupation, it should not be impossible to make fiscal arrangements

whereby this fraudulent undercutting could be prevented.

(3) The researches on synthetic dyes have not engrossed the attention of continental chemists to the exclusion of the study of natural colouring matters, and the present monograph, well printed on paper of pre-War quality, is a good indication of the interest taken by Swiss chemists in the border-line science of biochemistry. The subjects dealt with include a summary of the methods employed in obtaining balsams and resins and in subjecting these materials to systematic decompositions. The appropriate methods of proximate analysis are also indicated. The larger section of the work is devoted to the identification and preparation of the most important vegetable colouring matters. The detailed information supplied on this abstruse subject is supplemented by many references to original memoirs, and there is an adequate index. The brochure is the eighty-fourth section of the comprehensive handbook of experimental methods in biology being issued under the editorship of Dr. Emil Abderhalden, the well-known physiologist.

Relativity Problems.

Sidelights on Relativity. By Prof. A. Einstein. I. Ether and Relativity. II. Geometry and Experience. Translated by Dr. G. B. Jeffery and Dr. W. Perrett. Pp. iv+56. (London: Methuen and Co., Ltd., 1922). 3*s.* 6*d.* net.

PARTICULARLY since the introduction of the theory of relativity, the problem of the ether has been a bone of contention among physicists. They have been divided into two camps; one unwilling to let go the idea of an ether, though perhaps in modified form, and the other seeing in the theory of relativity, if not the negation of an ether, at least something that rendered it no longer necessary. In view of this, it is to be welcomed that Prof. Einstein's inaugural lecture on "Ether and the Theory of Relativity," which was delivered in 1920 at the University of Leyden, has been made accessible to the English scientific public.

"The endeavour toward a unified view of the nature of forces leads to the hypothesis of an ether," and in the first lecture in this book is to be found an excellent account of the various phases through which the ether-conception passed in the forward trend of physical research. The ether gradually became divested of its mechanical properties until, with the advent of the special theory of relativity, it was deprived of the "last mechanical characteristic which Lorentz had still left it"—its "immobility." But "to deny the ether is ultimately to assume that empty space has no physical qualities whatever," a view with which the fundamental facts of mechanics do not harmonise.

"According to the general theory of relativity space is endowed with physical qualities; in this sense, therefore, there exists an ether. According to the general theory of relativity space without ether is unthinkable; for in such space there would not only be no propagation of light, but also no possibility of existence for standards of space and time (measuring-rods and clocks), nor therefore any space-time intervals in the physical sense. But this ether may not be thought of as endowed with the quality characteristic of ponderable media, as consisting of parts which may be tracked through time. The idea of motion may not be applied to it."

The second lecture, on "Geometry and Experience," is an expanded form of an address delivered in 1921 to the Prussian Academy of Science in Berlin. In geometry, "axioms are free creations of the human mind. All other propositions of geometry are logical inferences from the axioms," and "the matter of which geometry treats is first defined by the axioms," or what Schlick aptly calls "implicit definitions." But geometry first becomes a natural science "by the co-ordination of real objects of experience with the empty conceptual framework of axiomatic geometry." "Geometry predicates nothing about the relations of real things, but only geometry together with the purport of physical laws can do so." The question as to the nature of the structure of a continuum is a physical one to which experience must supply the answer, and we must acknowledge Riemann's geometry to be correct "if the laws of disposition of practically rigid bodies are transformable into those of the bodies of Euclidean geometry with an exactitude which increases in proportion as the dimensions of the part of space-time under consideration are diminished."

The question of the spatial finiteness or otherwise of the universe appears to be definitely a "pregnant question in the sense of practical geometry." Einstein discusses this problem in its various aspects from the view-point of the results of the general theory of relativity, and shows how, by the use of an analogy in two dimensions, we may form a mental picture of a three-dimensional universe which is finite, yet unbounded, and not Euclidean, but spherical. He aims at showing "that the human faculty of visualisation is by no means bound to capitulate to non-Euclidean geometry."

To all lovers of logical and exact thought who are interested in the developments that have arisen in the wake of the theory of relativity, this book can be warmly recommended. The work of translation has been admirably done, and much of the *finesse* of expression characteristic of Einstein's writings has been retained.

Geographical Influences.

The Great Capitals: an Historical Geography. By Dr. Vaughan Cornish. Pp. xii+296. (London: Methuen and Co., Ltd., 1923.) 12s. 6d. net.

IT may be said at once that we regard this as one of the most important and original works in geography that have appeared within a generation. The volume should be looked upon by teachers of geography as essential to their studies. It cannot be denied that the book is not easy reading; it must have cost an immense amount of pains to write. The result is, however, worth the pains, and though readers who will follow every page with the aid of a good atlas may indeed find that they make but slow progress, they will be well rewarded for their labour and lose all desire to hurry through the interest roused by tracing the author's line of thought. There are no doubt many who, with the best will in the world, cannot find the necessary time to complete the study of the whole work. We would advise these first, if they must read the volume piecemeal, to keep it always at hand, and, second, at least to find the time to master the author's account, say, of the situation of Moscow (pp. 181-91) or London (pp. 211 and onwards). If one of these has been read with the necessary care, the reader, if he has been hitherto unfamiliar with the geographical point of view, can scarcely fail thenceforth to understand what geography means, and even professed geographers will be warned against one danger now rather prevalent arising from a too narrow study of "natural regions." Dr. Cornish never fails to take into account the wide-reaching influences on the rise and growth of towns.

The author's views on the special subject of his volume are set forth in his preface as follows:

"An historical examination of imperial capitals shows that their district is usually either a Storehouse, or a far-reaching Crossways near a Storehouse, seldom a Stronghold. Their political geography has one outstanding character, a forward, as distinguished from a central, site. The Great Power both of ancient and modern times has always been an incorporation of several States, and the characteristic site of the imperial capital is in or adjacent to that Storehouse of the dominant community of the empire which is nearest to the principal foreign neighbour."

This position the author endeavours to make good by ranging over all recorded time and the greater part of the world, examining his thesis in the light of the earlier and later history and geography of China, Japan, India, Persia, Mesopotamia, Italy and the Roman Empire of the West and East, Trans-Alpine Europe, North and South America, taking every opportunity presenting itself in the course of his investigation to show the infinite variety of ways in which geographical factors affect history and the course of events brings about changes in geographical values. On the whole, he may be said to have made out his case, and at any rate he has always something ingenious and interesting to say in support of it, not least when he is applying his theory to certain minor illustrations, as in dealing with the capitals of the "heptarchy" or the Iroquois capitals in the neighbourhood of the great lakes of North America. But he is not dogmatic. He will sometimes qualify his averments by an "I think" or "I suppose," and the very fulness with which he brings forward his arguments is an invitation to the student to judge before accepting, in Bacon's language "to weigh and consider."

If here and there are found some rather broad and questionable historical statements, the student should note that the validity of the geographical exposition is not necessarily affected thereby. The present reviewer lays no claim to any intimate knowledge of Indian history, but was rather startled on meeting with the statement (p. 28) that "twice in the course of history has a government seated and independent of foreign control, ruled the whole, or nearly the whole, peninsula," and he cannot find that it is fairly justified; but that does not affect the value of the author's geographical considerations as to Patna, the capital of "the Aryan Empire," or Delhi, that of "the Empire of the Mohammedan Moghuls."

The volume is illustrated by two maps, one showing "The Isothermal Frontier of Ancient Cities," the other "The Marmora Metropolitan Region." A few more maps of the latter kind would have assisted the student greatly. GEO. G. CHISHOLM.

Our Bookshelf.

Atoms. By T. C. Wignall and G. D. Knox. Pp. 288. (London: Mills and Boon, Ltd., 1923.) 7s. 6d. net.
White Lightning. By Edwin Herbert Lewis. Pp. iv+354. (Chicago: Covici-McGee, 1923.) n.p.

THESE two scientific novels both centre around the idea of liberating the energy of the atom—a theme first explored by Mr. H. G. Wells in "The World Set Free." They may be taken as indicative of the interest being taken by the public in the recent developments of physical science.

The first, "Atoms," a highly imaginative romance, reflects strongly some of the most cherished popular conceptions or misconceptions about the growth of science. Super-financiers contend with one another and with or through the regular international anarchist associations in an atmosphere of dynamite plots, assassinations, and impersonations, in order to corner the world's supplies of energy. A colossal plant for producing power from coal and distributing it by wireless springs up at the word of command, and is converted during erection into an atomic energy plant by the discovery of *sublimium*. Sublimium dis-

integrates everything it comes into contact with except *refracton*, and it is conveyed in capillary tubes of the latter, a metre thick in the wall, in minute quantities from the laboratory to the furnaces. The authors are clever enough to get the best out of both possible worlds, and succeed, not only in showing us the effects of Paris being converted into an inferno through anarchists blowing up the refracton tubes, but also at the same time to bring the venture to a brilliantly successful conclusion with the hero and heroine happily off for the honeymoon.

"White Lightning" is a most curious production. Each of its ninety-two chapters is named after one of the elements in the order of the Periodic Table, and, in most of the chapters, the author succeeds in bringing in some interesting allusion to modern discoveries in chemistry and physics, if not always specially connected with the titular deity of the chapter. The style is irritatingly disconnected and inconsequent, but it manages to convey some idea of the fascination and glamour of discovery and the enthusiasms of which it is born. Emanating from America, it is no surprise to find that this author's *dénouement* is to endow, through the generosity of his public-spirited characters, the hero and the heroine with a research laboratory to be devoted to the study of the liberation of atomic energy.

F. S.

The Great Flint Implements of Cromer, Norfolk. By J. Reid Moir. (Printed and published on behalf of the author for private circulation.) Pp. 39. (Ipswich: W. E. Harrison, 1923.)

The title of this book is scarcely adequate, for the work treats of many periods, from that of the "eoliths" to neolithic times. Many of Mr. Moir's views were at first regarded with profound scepticism, but are being accepted by an ever-increasing number of competent judges at home and abroad. In the work before us they are briefly summarised, but the account is too condensed to do justice to the author's discoveries. We hope that in the not distant future he will write a detailed work on the pre-history of East Anglia, and that it will be illustrated by Mr. E. T. Lingwood, the excellence of whose illustrations in the work before us is noteworthy.

Three important questions arise with regard to the Cromer flints here described: (1) Are they derived from Pliocene beds? (2) Are they artefacts? (3) If they are, to which cultural period do they belong? The evidence bearing upon the first two questions is only summarised in the work before us, though more fully stated in papers to which reference is made. After reading that evidence, and after a visit to the spot under the author's guidance, the reviewer is of opinion that Mr. Moir is correct in his contention that the flints were once embedded in a Pliocene pebble-deposit, and that many of them are undoubted artefacts. Stress is laid upon the last point, as the specimens figured here will probably be regarded with suspicion by sceptics, and many others which are not figured are more convincing.

The reference to the early Chellean period is regarded only as a probability by the author, but perusal of this and other of his writings leads one to consider that he has made out a good case in favour of this probability.

The Happy Traveller: a Book for Poor Men. By the Rev. Frank Tatchell. Pp. xii+271. (London: Methuen and Co., Ltd., 1923.) 7*s.* 6*d.* net.

The author of this distinctly original book is a Sussex vicar, and we can picture him setting out for Hierusalem from the Middeherst of the twelfth century, in robust amity with all whom he might meet upon the way. Once outside the door of home (p. vii), he is never conscious of an obstacle. Like the young Jesuit Thomas Stevens, whose letter is preserved by Hakluyt, he is going to see his first shark, his first flying-fish (p. 140), and to learn, by personal encounter, the essential glory of the earth. Even between the poplars of a *route nationale* Mr. Tatchell goes on foot. He is forced to embark on liners for the greater seas; but he has travelled as a steerage passenger and as a steward, and we learn that "the 'deck' passages on Japanese boats are especially good."

The lists of common phrases in foreign languages might well have been omitted. We cannot judge the Burmese and the six words of Papuan, and they may be "happier" than the French. Yet we should be sorry to lose the conversation between the vicar-designate and the Fijian damsel on pp. 225-6. The notes on local customs are always helpful, and are backed by a truly catholic philosophy. Touches like the following add a sparkle to the printed page. "If you want to preserve your illusions, do not visit Palestine" (p. iv). "Should you be attacked by a mob in the East, hurt one of the crowd and hurt him quickly" (p. 23). "If you are in the steerage, take also some fruit and jam and a bottle of rum, which nowhere tastes so well as at sea" (p. 139). R. L. Stevenson would have enjoyed this passage, and he would have endorsed the maxim on p. 7: "The beaten track is the best track, but devote most of your time to the by-ways."

G. A. J. C.

The Coconut Palm: the Science and Practice of Coconut Cultivation. By H. C. Sampson. Pp. xv+262+40 plates. (London: J. Bale, Sons, and Danielsson, Ltd., 1923.) 31*s.* 6*d.* net.

This book is a welcome departure from the usual type of manual that deals in generalities about the plant concerned, with a fuller account of the methods of cultivation. Its author is to be congratulated upon having broken new ground, and it is by such study as is described in this volume that we may hope to arrive in time at a really scientific method of cultivating and treating the palm. Detailed scientific observations are given, for example, upon the numbers, the direction of growth, and the behaviour of the roots, a subject upon which we have usually had only vague generalities to go upon. Many other subjects are treated in the same way, *e.g.* the flowering, the relative proportions of flowers that set fruit, and so on.

The second part of the book deals with plantation management, and gives a very good, clear, and well-reasoned account of the methods in use, and the reasons for them—an account which will repay study even by the experienced coconut planter. In Part III. the products of the coconut palm are dealt with, and the methods of preparation employed in South India, the coconut products of which command the highest

prices, are considered and discussed, and the reasons for the treatment are pointed out.

The book is the best that we have seen treating of the coconut palm, and should be in the hands of every one interested in the industry.

Department of Applied Statistics (Computing Section), University of London, University College. Tracts for Computers. (1) No. 4: *Tables of the Logarithms of the Complete Γ-Function to Twelve Figures.* Originally computed by A. M. Legendre. Pp. iv + 10. 1921. (2) No. 8: *Table of the Logarithms of the Complete Γ-Function (for Arguments 2 to 1200, i.e. beyond Legendre's Range.)* By Egon S. Pearson. Pp. x + 16. 1922. (3) No. 9: *Log Γ(x) from x = 1 to 50·9 by intervals of ·01.* By Dr. John Brownlee. Pp. 23. 1923. (London: Cambridge University Press, 1923.) 3*s*. 9*d*. net each.

(1) THIS tract gives a reprint of Legendre's table originally published in the (now rare) second volume of his "Traité des fonctions elliptiques" (1825). It records the numerical value of $\log_{10} \Gamma(p)$ from 1·000 to 2·000, at intervals of 0·001, to twelve places of decimals, together with the first, second, and third differences for interpolation.

(2) In the second tract before us we have $\log_{10} \Gamma(p)$, correct to ten decimal places, for values of p at intervals of 0·1 from 2·0 to 5·0, of 0·2 from 5·0 to 70·0, and of a unit from 70 to 1200. Second and fourth differences are tabulated also, giving all necessary assistance in evaluating the function for intermediate values of p. From the last entry it can be inferred that Γ(1200), or 1199 !, is an integer of 3173 digits.

(3) Finally we have $\log_{10} \Gamma(p)$ tabulated to seven decimals at intervals of 0·01 from 1·0 to 50·9. This pamphlet rounds off the work on the Γ-function in the present series of tracts.

The Diseases of the Tea Bush. By T. Petch. Pp. xii + 220. (London: Macmillan and Co., Ltd., 1923.) 20*s*. net.

THIRTY years ago planters were inclined, when an outbreak of disease occurred among their crops, to conceal it from general knowledge or observation as much as possible, the result being that little or nothing was known, from a scientific point of view, of the diseases attacking tea. As time has gone on, however, this has altered. Watt and Mann, in 1903, described about a dozen diseases, and in the present volume the number has increased to about sixty. Whether more harm is now being done by disease, however, is very doubtful; on the whole it is perhaps less.

The book is prefaced by one of the simplest and best introductions to the study of fungi that we have yet seen. The diseases are treated in order, according to whether they attack leaves only, leaf and stem, stem, or root; and for each disease the characteristic manifestations are described, with excellent figures of the most important, while at the end of the book instructions are given for the preparation of Bordeaux and other fungicidal mixtures for spraying—a treatment which has come into considerable use during recent years, and leaves but an infinitesimal trace of copper in the tea.

Bau und Entstehung der Alpen. Von Prof. Dr. L. Kober. Pp. iv + 283 + 8 Tafeln. (Berlin: Gebrüder Borntraeger, 1923.) 12*s*.

Two years ago attention was directed to Prof. L. Kober's view that folded mountain-chains are marginal features of a geosynclinal "orogen" nipped between two mutually approaching masses of "kratogen" in the depths (NATURE, vol. 108, October 20, 1921, p. 236). The present work embodies a lucid review of the researches of the last forty years in the Alpine region, which is intimately known to the author from the Pennines to the Transylvanian wall. Through all details, however, he maintains his outlook on the world at large. In neat diagrams he shows how a dual structure is traceable in the western United States, in the Caledonian orogen of Scotland and Scandinavia, and in the axis of Japan. The floor of the Tethys channel (Fig. 2) has been squeezed up here and there to form mountain bulges from Andalusia to Sumatra, over a distance of 14,000 km. In the Alpine region only, a one-sided character has been imparted to the mountain-mass, and this is due to the fact that the southern marginal range, the Dunaric, has been moved northward until part of it overlies the east Alpine sheet. In agreement with H. Roothaan (1918), Prof. Kober (p. 252) places the beginning of Alpine overfolding in Cretaceous times, and the main movements in the Oligocene period. To quote the final words of this stimulating volume, "noch manche Rätsel bergen die Alpen."

G. A. J. C.

Colour Index. Edited by Dr. F. M. Rowe. Part 1. Pp. viii + 48. (Bradford: Society of Dyers and Colourists, n.d.) n.p.

THIS is the first part of a work that is being published, in fourteen monthly parts, by the Society of Dyers and Colourists, Bradford, with the object of making available, in the English language, to dye users and all interested in colouring matters, the latest information concerning commercial dyes, their constitution, modes of preparation, and uses.

Part 1 deals with the nitroso, the nitro, and a portion of the azo colours, while it is understood that when the work is completed it will contain descriptions of some 1300 distinct synthetic colouring matters.

The information is set out in tabular form, closely resembling that used in the well-known "Farbstofftabellen" of Schultz, but with the welcome addition of ample space for notes, and brought up-to-date by the inclusion of much information that is lacking in the "Farbstofftabellen."

It is well produced, and is a work that should be in the hands of all who are interested in colouring matters, whether from a scientific or practical point of view.

The Birth of Psyche. By L. Charles-Baudouin. Translated by F. Rothwell. Pp. xxiii + 211. (London: G. Routledge and Sons, Ltd.; New York: E. P. Dutton and Co., 1923.) 5*s*. net.

A SELECTION of short memories of childhood written as prose poems with a distinct consciousness of scientific value in their significance. The author has written a preface to the English translation, in which he defends the presentation of scientific material in poetical form.

Letters to the Editor.

Photochemical Production of Formaldehyde.

IN a recent paper (J. Amer. Chem. Soc., 45, 1184 (1923)) Spoehr states that he has been entirely unable to reproduce our results on the photochemical production of formaldehyde from carbon dioxide and water (Trans. Chem. Soc., 119, 1025 (1921)), and he invites us to describe our experimental methods in greater detail than we did in our original communication. Before replying to this invitation we have repeated all our experiments and the new results entirely confirm the old, and there seems, therefore, to be little or no doubt that by the action of short wave ultra-violet light on aqueous solutions of carbonic acid formaldehyde is formed.

The quartz mercury lamps employed in all our investigations are the U form made by the Hewittic Company and the current taken by each lamp is 3·5 amps. at 230 volts. About 75 c.c. of pure conductivity water were placed in a transparent quartz test tube 9 × 1 in., and a slow stream of carbon dioxide, prepared from pure marble and synthetic hydrochloric acid and washed with a solution of potassium bicarbonate, was passed through the water. The carbonic acid solution was kept cool by a narrow tube through which a stream of cold water was passed. Stringent precautions were taken to guard against contamination by organic matter, and the times of exposure varied from 18 to 72 hours. Since the most satisfactory test for formaldehyde appears to be Schryver's test we have used it in every case, and throughout the whole series of observations we carried out control blank experiments. The results obtained may be summarised as follows :—

1. No formaldehyde can be detected in the solutions if the distance between the lamp and test tubes is less than six inches and no screen is interposed.
2. Formaldehyde can be detected in the solutions if the distance between the lamp and test tubes is six inches or more.
3. The quantity of formaldehyde formed is increased if a plate of calcite is interposed, and in this case the distance between the lamp and test tubes can be reduced with advantage.
4. The quantity of formaldehyde found is increased if the solution contains calcium or potassium bicarbonate.

The amount of formaldehyde found, though absolutely definite, is very small (1 to 2 parts in 100,000), the reason for this being twofold. The absorption band of carbonic acid lies near to $\lambda = 220\mu\mu$ and the intensity of the radiation of the mercury lamp at or about this wave-length is exceedingly small, so that the velocity of formation of formaldehyde must necessarily be very slow, even assuming that the whole of the radiation is absorbed. A second factor is that formaldehyde in dilute aqueous solution is decomposed by very short wave-length light. Indeed, a 0·01 per cent. solution of formaldehyde through which carbon dioxide is passed is entirely decomposed in 24 hours if placed at a distance of 4 inches from the quartz mercury lamp. It follows, therefore, that the formaldehyde found in the solutions described above is only the excess of that formed over that decomposed. The very short wave-length radiations are more absorbed by air than is light of wave-length $220\mu\mu$, and thus an explanation is found of the fact that a minimum distance between reaction vessel and quartz lamp is necessary for positive evidence to be obtained of the production of formaldehyde. Since calcite absorbs all rays of shorter wave-length than $215\mu\mu$, the amount of formaldehyde is increased if a calcite screen is interposed and the minimum distance between lamp and test tube becomes no longer necessary.

In view of our two series of positive results it is surprising that Spoehr finds himself unable to confirm this reaction, since the evidence we have obtained seems to us to be conclusive. In his paper Spoehr states that he used the straight form of mercury lamp, and in this may be found a possible explanation of the failure which he has recorded. It is a known fact that the quartz mercury lamp deteriorates after use and loses its power of radiating short wave ultra-violet light. Prof. Allmand has proved this deterioration of a mercury lamp of the straight form and has been kind enough to communicate his results to us. It may be suggested that this fact explains Spoehr's failure to observe any formaldehyde, the necessary ultra-violet radiation from his lamps being too small in amount. We have noted that the U-shaped lamp does not deteriorate, or, if so, very slowly, since our lamps after many months' continuous use still ozonise the oxygen of the surrounding air, a photochemical reaction which is known to be stimulated by very short wave-length light ($\lambda = 200\mu\mu$).

The great dilution of the formaldehyde necessitates the use of a colorimetric test for its detection. In view of Willstätter's statement that the Schryver test is given only by formaldehyde and hexylenic aldehyde, this reaction has commonly been accepted as positive evidence for formaldehyde. We have, therefore, employed this test, having at the same time proved for our own satisfaction that it certainly is capable of detecting formaldehyde at concentrations of 1 in 1,000,000.

Correlation of Upper Air Variables.

IN view of the importance of the subject, a few remarks with regard to the note in NATURE of May 19, p. 684, on "Correlation of Upper Air Variables" may perhaps be permitted me, chiefly with the object of making clear the real issues in this question. Dines [1] found very high coefficients of correlation (of the order of 0·8) between various upper air variables, specially with pressure at 9-kilometre level. This led to the formulation of the Dines-Shaw theory of the sub-stratosphere and the regions above 9 kilometres as the real seat of origin of meteorological causes. In 1920, Chapman [2] applied certain statistical corrections to the coefficients of correlation found by Dines and raised these to +1·00 in several instances. A correlation of +1·00 establishes absolute causal nexus. A conclusion of this nature demands close scrutiny, specially as it is being widely quoted and applied in current writings.[3] In a recent memoir [4] noticed in NATURE [5] I have examined the statistical analysis in some detail.

As regards Chapman's work, my chief criticism is this: he has neglected entirely the effect of correlation between "errors" of measurement. Taking

[1] M.O. No. 210*b*, Geophys. Mem. 2, 1912; M.O. No. 220*c*, Geophys. Mem. 13, 1919, etc.
[2] Proc. Roy. Soc. 98 A (1920), pp. 235-248.
[3] M.O. No. 220*i*, Geophys. Mem. 19, p. 215; Sir Napier Shaw, "The Birth and Death of Cyclones."
[4] Mem. Ind. Met. Dept., vol. xxiv. Part ii., "On Errors of Observation and Upper Air Relationships."
[5] NATURE, May 19, 1923, p. 684.

these into consideration, my analysis shows that: (A) the statistical correction may easily become negative; that is, the true correlation may be considerably lower than the observed correlation. On the other hand, if "errors" are independent (or as my analysis shows, for particular values of correlation between errors), then (B) the correlation may be positive as found by Chapman, and the true correlation higher than the observed. The question is: under which category (A) or (B) above does the work of Dines fall?

In the case of a balloon meteograph, all measurements are made on one and the same trace,[6] and the heights are calculated with the help of Laplace's formula.[7] This formula involves both pressure and temperature, and a detailed examination shows that it serves to introduce, through "interpolation," correlation between errors of measurement in pressure and temperature. Besides this "interpolation" effect, correlation may also be introduced through what Karl Pearson[8] calls the "atmosphere" of measurement and through correlation of successive judgments.[9] It is, therefore, not improbable that Dines's work falls under (A) and gives values of correlation coefficients higher than their true values. My contention is this: (C) in the absence of definite proof that Dines's work falls under (B), Chapman's corrections cannot be accepted as real, and, to be on the safe side, Dines's coefficients must be looked upon as giving superior limits to the true correlation.

Douglas[10] found the values of correlation between pressure and temperature at 10,000 feet to be 0·65, which is considerably lower than Dines's figure 0·77 (and still more so than Chapman's corrected value). I quoted Douglas's result, as I thought his work to be free from the peculiar "interpolation" correlation introduced by the use of Laplace's formula. On this view, Douglas's work would probably come under (B) and would give values of correlation lower than true values. I now find stated in the note in NATURE that I have fallen into error in thinking "that Douglas's coefficients are based on true heights." (The fault, however, is scarcely mine, for Douglas himself definitely stated[11] that his observations "refer to actual heights above mean sea-level, and not to aneroid heights.") On the present view, Douglas's work also would probably come under (A) above, and even 0·65 would seem to be too high a value for the true correlation. This corroborates my contention (C) that Dines's coefficients are probably too high. It is, therefore, clear that the rectification of my error has further strengthened my conclusion. I may note in passing that the low values of the coefficients obtained by Douglas may be easily explained in accordance with my analysis if we assume that the magnitude of the correlations between errors of measurement are lower in his case.

In my other memoir[12] I pointed out certain statistical discrepancies in the coefficients published by Dines. It is stated in the note in NATURE that I seem "to have confused the T_m used by Dines, namely, the mean temperature between 1 and 9 kilometres, with the mean temperature between 0 and 9 kilometres," and that this supposed confusion on my part "fully explains the discrepancies" noted by me. I am unable to agree with this, as I do not think I have made any confusion between the two mean temperatures referred to above. On p. 1 and p. 3 of my memoir I have explained clearly that T_s represents the mean temperature between 0 and Z kilometres, and I have kept T_s and T_m distinct throughout. It is true I have substituted $dT_s = dT_m$, but this is quite different from putting $T_s = T_m$, since dT_s and dT_m are both statistical differences (which would ultimately be summed and averaged out) and not analytic differentials. This substitution is further discussed on p. 6 of my memoir. Now if this substitution is justified, then it follows from Laplace's equation that: (D) in the case of the figures published by Dines it is actually possible to obtain higher values of the correlation coefficients at levels considerably lower than 9 kilometres. In view of the assumption involved it is, however, necessary to test (D) by direct examination of the data concerned. But in the absence of such examination it is not sufficient to state that "discrepancies can be explained."

[6] M.O. No. 210*f*, Geophys. Mem. 6, 1914.
[7] M.O. No. 223, "Computer's Handbook," Section 2.
[8] Phil. Trans. 198 A, 1902, "Errors of Judgment," etc.
[9] Egon S. Pearson, *Biometrika*, xiv., 1922.
[10] Quar. Jour. Met. Soc., xlvii., January 1921, p. 28, etc.
[11] *Ibid.* p. 25.
[12] Mem. Ind. Met. Dept., vol. xxiv. Part I., "The Seat of Activity in the Upper Air."

To sum up, the main problem is to find (*a*) the true correlation, and (*b*) the region of the best correlation in the case of upper air variables. It would seem that in view of (A), (C), and (D) above, the work of Dines and Chapman (which is flatly contradicted by that of Douglas) cannot be accepted as final either as regards (*a*) or as regards (*b*). Further advance is not possible without a thorough statistical scrutiny of the original data.

May I, therefore, suggest that (i.) the original material of Dines and Douglas (as well as other fresh material, if available) be published with clear statements about methods of measurement employed and actual formulæ (rigid or otherwise) used for computation of heights, and that (ii.) such material be submitted to some statistical expert like Prof. Karl Pearson for examination and report.

P. C. MAHALANOBIS.

Presidency College, Calcutta,
June 20.

THE results of the British Registering Balloon Ascents are published in full by the Meteorological Office in the Annual Supplement to the *Geophysical Journal*. A full description of the instruments, methods, and formulæ used have also been published by the M.O., and will be found in the "Computer's Handbook," M.O. 223, Section II., subsection ii. They are open to anybody for use, and if Prof. Mahalanobis will carry out the computation he desires he will earn the thanks of meteorologists.

It is difficult, however, to see how Prof. Mahalanobis can obtain a perfectly correct correlation coefficient, in view of the fact that, with a coefficient of 0·70 based on 400 observations, the causal standard error is as high as 0·025. This fact suffices to explain the differences between Dines's and Douglas's results, which can scarcely be called a "flat contradiction."

With reference to Prof. Mahalanobis' assumption, that $dT_s = dT_m$, it may be pointed out that the result of making this assumption is discussed in the papers to which he referred, and also that no claim to extreme accuracy in the correlation coefficient is made by Dines. (See M.O. 210*b*, bottom of p. 43, and p. 44, line 11; also *Beiträge zur Physik der freien Atmosphäre*, V. Band, Heft 4, pp. 222, 223, and 225.)

THE WRITER OF THE NOTE.

Tubular Cavities in Sarsens.

WITH regard to Mr. F. Chapman's letter on the probable æolian origin of sarsen rock (NATURE, August 18, p. 239), and his reference therein to my previous note, may I say that I was not referring to

the holes so frequently present in the blocks—which I was told, when a student at the Royal School of Mines, some forty years ago, might be due to the presence of roots and rootlets in the sand before consolidation—but to a special case in which all the details *suggested*, from my previous knowledge of such things, the work of marine or esturine annelids. Without having seen what I saw, Mr. Chapman questions the validity of the grounds for the suggestion.

There is no evidence that the blocks to which I referred originated in the Bagshot Sands. They may have been associated with the Reading beds.

Assuming that all the tubular cavities in sarsens were caused through the presence of roots and rootlets in the original sand, what evidence is there that such roots grew *in situ*? It may have been driftwood. Plenty of such wood is to be found, in a lignitic and pyritised condition, in some of the Bagshot beds. I have seen some sarsen rock passing into conglomerate, indicating the proximity of littoral conditions.

It would be of interest to know if Mr. Chapman has found any grains of comminuted land shells, burrows and bones of animals, and burrows and remains of insects in the consolidated dune-rock he describes.

Barometric Pressure in High Latitudes.

MR. R. M. DEELEY'S reply in NATURE of August 18 to my letter in the issue of June 21 does not meet my objection, and since he repeats the misleading statement that surface pressure is low at the poles it seems desirable to come to a closer definition of terms. In my letter I made it clear that surface pressure was to be regarded "high" at the poles, not so much in relation to the absolute value as with respect to the belt of minimum pressure—the theatre of maximum cyclonic activity—about latitude 60° N. or S.; but Mr. Deeley under the general term "Arctic regions" does not distinguish between the sub-polar regions about 60° N. or S. and the true polar regions about 90° N. or S.

In maps produced by the late Prof. H. Mohn in his masterly discussion of the scientific results of the *Fram* expedition of 1893–96, which confirm in a remarkable way previous work of the late Dr. A. Buchan (see, for example, "Encycl. Britannica," 1911 edn., Polar Regions), it is shown that in winter a ridge of high pressure (over 762 mm.) is located across the North Polar basin connecting the great Canadian and Siberian high pressure areas, and separating the deep barometric minima of Bering Sea and Iceland (748 mm.), and that this is the season when the pressure gradient is steepest on the north side of these minima, just as it is on the south side. Dr. G. C. Simpson's maps embodied in his famous Antarctic volume are no less emphatic about relatively high surface pressure around the South Pole, even on that part of the area which is high plateau, and the fact that the expression "Antarctic Anticyclone" is nowadays a household word among meteorologists, geographers, and geologists alike ought to prevent unqualified statements to the effect that the South Pole is a centre of low surface pressure. It has been found that towards both poles pressure decreases from lat. 40° N. or S. at the height of about 6000 feet, but at the surface the total effect of all layers is to produce that slight excess of pressure which permits the polar outflow of air which Mr. Deeley admits does take place.

Mr. Deeley then goes on to say that he has attempted to explain why these outflowing polar winds do not reach low latitudes. But any one who thinks in terms of daily weather changes instead of in the cast-iron terms of average wind and pressure charts must realise that polar currents *do* have abundant opportunity of reaching low latitudes at irregular intervals, this, furthermore, being a foremost point in the theory of Prof. Bjerknes. There is nothing which so paralyses meteorological thought as the habit of regarding mean charts as though they represented actual unchanging conditions rather than merely the generalised expression of conditions which are perpetually varying to such an extent that the average type depicted is comparatively seldom realised, is generally to a greater or lesser extent distorted, and occasionally altogether subverted or inverted, as during our spells of east wind in the belt of "westerlies."

Finally, whatever effect the stratosphere may have on pressure at sea-level, Mr. Deeley appears to forget that the broad facts of low winter pressure over the oceans and high continental pressure are mutually complementary, as also the reverse distribution of high summer oceanic pressure and low continental pressure, and are well known to be due to seasonal contrasts of surface temperature, the difference of both pressure and temperature being greater in winter.

Is there a Change of Wave-length on Reflection of X-rays from Crystals?

A. H. COMPTON (*Phys. Rev.*, 21, 207) has recently shown that there is a change of wave-length when X-rays are scattered by an amorphous substance. If reflection of X-rays from crystals is a special case of scattering it would seem that there might be also a change of wave-length on reflection. Assuming such a wave-length change, we have for reflection from a single plane of atoms

$$(1) \quad . \quad . \quad . \quad . \quad \frac{\cos\theta_1}{\lambda_1}=\frac{\cos\theta_2}{\lambda_2},$$

where λ_1 and λ_2 are the incident and reflected wave-lengths and θ_1 and θ_2 are the grazing angles of incidence and reflection respectively. For reflection from successive planes of atoms we have

$$(2) \quad . \quad . \quad . \quad \frac{d\sin\theta_1}{\lambda_1}+\frac{d\sin\theta_2}{\lambda_2}=n,$$

where d is the grating space of the crystal and n is the number of vibrations (an integer) difference between the waves reflected from two consecutive planes. Also we have Compton's change of wave-length formula

$$(3) \quad . \quad . \quad . \quad \lambda_2=\lambda_1+2\gamma\sin^2(\theta_1+\theta_2)/2,$$

where $\gamma=h/mc=0{\cdot}024$ Å.U.

From these three relations the formula for the incident wave-length λ_1 can be found in terms of d and θ_1, which is the angle measured experimentally. Let λ' be the apparent wave-length obtained from Bragg's law $n\lambda'=2d\sin\theta_1$. The relation between λ' and λ_1 is found to be

$$(4) \quad . \quad . \quad . \quad \lambda'=\lambda_1+\gamma-\frac{\gamma^2\sin^2\theta_1}{\lambda_1+\gamma}.$$

From this it appears that λ' is greater than λ_1, the true wave-length, by about 0·024 Å.U. Also it appears that λ' is less for higher orders of reflection, a result

which has been observed experimentally by Stenström and also by Duane and Patterson (*Phys. Rev.*, 16, 532). The latter find that the difference between the values of λ' when the tungsten line 1·473 Å.U. is reflected in the first and second orders from calcite is 0·00015 ± 0·00009 Å.U. Formula (4) gives a difference of 0·00007 Å.U., which is within experimental error of the observed difference. However, this difference may also be explained on the assumption of a refractive index for X-rays.

X-ray wave-lengths are also measured by observing the angle of deviation $(\theta_1+\theta_2)$ between the reflected and incident ray. This is particularly the case when the photographic method is used (Siegbahn, Dershem, Overn and others). Let λ'' be the apparent wave-length when $\theta_1+\theta_2$ is observed so that $n\lambda''=2d \sin(\theta_1+\theta_2)/2$. We now have a difference between λ' and λ'' on our theory given by

$$(5) \quad . \quad . \quad . \quad . \quad \lambda' - \lambda'' = \gamma \cos^2 \theta_1$$

to the first power of γ. For the lower orders of reflection this difference is approximately 0·024 Å.U., which should be easily observable. Overn (*Phys. Rev.*, 14, 137) has found λ'' for the above line. Comparing with Duane and Patterson's value of λ' for the same line we find the experimental value of $\lambda'-\lambda''$ to be 0·0005 Å.U., which is within experimental error of zero. This would seem to be decisive evidence that there is no change of wave-length when X-rays are reflected from a crystal.

On the Structure of the Molecule.

THE difficulty of reconciling the atomic systems of Bohr and of Langmuir, and of accounting for the attraction between atoms to form molecules and chemical compounds, might perhaps be elucidated in the following way.

If the analogy between atomic structure and astronomical planetary systems holds good, the atom is essentially a two-dimensional figure, while matter, which is composed of atoms, is essentially three-dimensional.

If then combination takes place between two or more atoms, it would be reasonable to suppose that

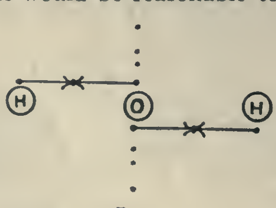

FIG. 1.

this does not take place in the same plane as the electronic orbit—an idea which is borne out by the work of Bragg on crystal structure.

We may suppose combination to take place somewhat as follows, in the formation of H_2O :—

If the plane of electrons be represented in Fig. 1 by the dots, it would be quite possible, if an electron were to be drawn out of the normal plane of each atom as indicated by the arrows, for it to form part of two atoms while revolving in a similar orbit to the original one but, owing to its divided allegiance, in a different plane. It would seem, however, that it would very soon take up a position directly between the two nuclei, when it would become *static*.

In the case of hydrogen, which has only a sufficient positive charge in the nucleus to hold one negative electron, if we suppose two electrons to be drawn out of the plane—one from each atom—the projection from the oxygen atom would be negative in sign, forming a negative link between two positive nuclei. This would perhaps explain the quite unique position of hydrogen in chemical combinations.

The system could be applied quite readily to more complex molecules. Bragg's model of the tartaric acid molecule (see NATURE of June 9, Supplement, p. ix) is readily amenable to this way of treatment,

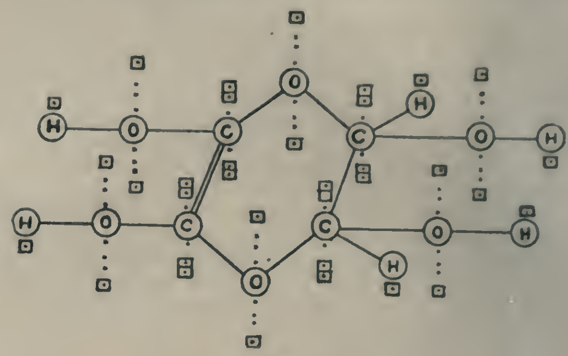

FIG. 2.

as the accompanying diagram (Fig. 2) will show, the electrons coming out of their respective systems being shown surrounded by a square.

It will be seen too from Sir W. Bragg's drawings that the links may easily be conceived as being in planes which would not interfere with the orbital motions of the remaining electrons.

The suggestion is then that, in the formation of the molecule, both dynamic and static electrons have their place, and this will throw considerable light on the nature of the links between the two or more positive nuclei.

A. PEARSE JENKIN.
Trewirgie, Redruth, July 20.

A Primitive Lens.

IF a wire of ½ to ¾ mm. diameter be bent into a closed circular loop of about 8 mm. diameter and dipped in water, or a transparent oil such as castor oil, a stable liquid film can be readily obtained covering the loop. A thin dished metal disc with a circular hole in the centre is a convenient alternative to the wire loop. Liquid can be easily added or removed without breaking the film, so as to vary the curvature of the liquid lens so formed. Such a lens, though far from perfect, may be made to give a magnifying power of nearly 5 over a small field.

It is conceivable that some of the very fine work done in Egypt, long before the invention of "optical" glass, may have been made possible by the use of a liquid lens of this kind. The phenomenon might easily have been accidentally observed; for even a drop of water lying on a greasy surface gives a small but appreciable magnification of the surface which it covers.

By using a thicker wire (about 2 mm. diameter) and less liquid, a diminishing lens may be made in the same way.

Baluchitherium osborni and its Relations.

By C. FORSTER-COOPER.

THE history of the discovery of the various fragments of Baluchitherium, which have enabled Prof. Osborn to make the preliminary restoration here reproduced (Fig. 5),[1] is interesting. In 1910 the present writer was fortunate enough to obtain bones of numerous extinct animals in the early Miocene deposits of Baluchistan. Nearly all of the animals were strange and, except for such of them as had previously been

FIG. 1.—Atlas of Baluchitherium with one of a modern rhinoceros.

obtained by Dr. Pilgrim of the Indian Geological Survey, were previously unknown. Among them an atlas, the first bone of the neck (Fig. 1) and an astragalus, one of the principal bones of the ankle, were of such astounding size as to proclaim themselves as belonging to an entirely new form of mammals, and one larger even than the elephant. Beyond the fact that the bones belonged to the Perissodactyla, a group which includes the horses, tapirs, and rhinoceroses, together with some extinct families, nothing further at the time could be said of them.

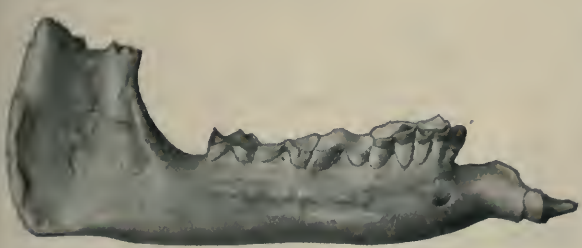

FIG. 2.—Lower jaws of Paraceratherium, showing the unusual feature, for a rhinoceros, of procumbent lower tusks. The length of the actual specimen is 30 inches.

During an expedition to the same place in the following year further remains were obtained, which comprised other vertebræ, limb and foot bones of this large animal, together with teeth of a large but primitive rhinoceros, some fairly complete skulls, and a lower jaw of a size to correspond with the skulls. The lower jaws, although obviously belonging to a rhinoceros of some sort, and one of considerable size, showed a unique feature in that the two front teeth were modified into a pair of stout, downwardly turned tusks (Fig. 2). Neither skulls nor jaws appeared to be of sufficient size to belong to the animal which possessed the atlas. In fact, the former animal appeared to be nearly twice the size, and on these grounds separate genera were made, Baluchitherium for the larger form and Paraceratherium for the smaller.

A few years later the Russian palæontologist Borissiak discovered the remains of a very similar large animal in Turkestan, which he named Indricotherium, but he likewise failed to get the skull. This regrettable lacuna in our knowledge has within the last few years been filled by the discovery of a nearly complete skull in Mongolia, a discovery which we owe to Granger, of the American Museum of Natural

FIG. 3.—Femur and humerus of Baluchitherium.

History's expedition to China. This skull is five feet in length, and thus all requirements as to size are abundantly filled, and with it enough bones from Baluchistan, Turkestan, and China (the wide separation of these areas shows the great range of distribution of the animal in former times) are known to enable us to make an approximate restoration, and to give us a reasonable idea of what the animal looked like while still alive.

Baluchitherium on reconstruction proves to be a very strange animal. The limbs are as large as those of an elephant, and in some points are not unlike them (Fig. 3). The feet, however, are entirely different in structure, the fingers and toes, of which there are only three to each foot, are much flattened, while the metacarpals and tarsals are enormously elongated (Fig. 4), so much so that the wrist is elevated nearly a yard above the ground, three times as high as the corresponding measurements in the elephant. Of the three toes, the central one is much the largest, the two lateral ones being pressed close to its sides, rather like the splint bones of the horse, though here the side toes are complete. There are some very curious, and as yet not fully understood resemblances to the horse in

[1] Prof. H. F. Osborn in *Natural History*, vol. xxiii. (New York), gives an excellent and fully illustrated account of Baluchitherium and its relations to other rhinoceroses. There is also a figure of the skull found in Mongolia.

certain of the foot bones, and notably in the neck. The neck bones, in fact, of all the many animals with which Baluchitherium has been compared, come

FIG. 4.—Toe bone of Baluchitherium, 15 inches long, with the corresponding bone of a modern rhinoceros for comparison. Larger bones than the one figured have been found.

nearest in proportions and shape, though of course not in size, to those of the horse. They show, however, one feature, which is unique in mammals and can only be paralleled in certain of the gigantic extinct reptiles, in that the lateral canals through which a blood-vessel runs are hollowed out into large cavities. These are so large that the central portion of the vertebra is reduced to a thin vertical partition, and in section [2] the bony parts of the centrum have a I shape; in fact Baluchitherium, in order to combine lightness with the necessary strength, has hit upon a design well known to engineers in the construction of girders.

Owing to the size of the limb bones and the height of the feet, Baluchitherium must have stood from twelve to thirteen feet from the ground, and with its horse-like neck and five-foot skull, an enormous skull length for a land mammal, must have had an over-all length of at least twenty-three feet! One curious point in all this bulk is that the head seems almost too small for the body!

The gigantic size of this animal can best be seen from the figures of Prof. Osborn [3] of his restoration of Baluchitherium (Fig. 5) compared with a white rhinoceros drawn to the same scale. It will be noticed that Baluchitherium, as restored, is considerably higher in the fore than in the hind quarters. This is a perfectly reasonable restoration on the assumption that the animal very probably fed upon the leaves of trees, but until the limb bones of a single animal are obtained it cannot be proved. An alternative restoration, also by Prof. Osborn, more on the lines of an ordinary rhinoceros, gives a somewhat different appearance.

The relationships of this animal are at present obscure.

It is certainly a rhinoceros, but unlike any known form, modern or ancient. In the teeth and skull, except for strong downwardly turned upper tusks, it is like the extinct hornless Aceratherine rhinoceroses, but the "horselike" features of the feet and neck preclude any close connexion. There is no suggestion of any but superficial resemblance to the horses, from which the tooth structure alone would at once exclude it. In fact it will be necessary to go back a long way in time to find the starting-point of Baluchitherium, and this point is at present unknown, although the present writer has suggested the little Eocene Triplopus, a rhinoceros-like animal with certain horse-like features in its limbs, as a possible signpost.

In his reconstruction Prof. Osborn has restored the fragment of lower jaw on the lines of the lower jaws of Paraceratherium (Fig. 2). The relations of these two forms are not yet clear. Baluchitherium is nearly twice the size of Paraceratherium, which is rather too large to be accounted for as a sexual difference. Moreover, there are a number of differences in

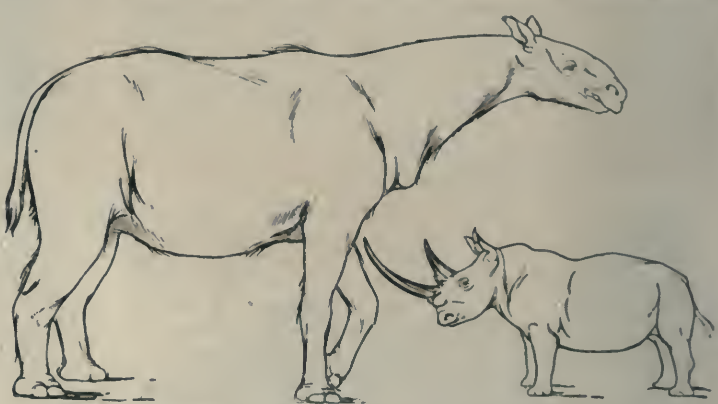

FIG. 5.—Restoration of Baluchitherium, with outline of the white rhinoceros for comparison. (After Osborn.)

the skull and teeth which render it probable that the forms are really different. It is much to be hoped that the American expedition will be successful in finding the front part of the lower jaw of Baluchitherium, which will go far to decide the point.

[2] A cast of one of these vertebræ in section, together with the original bones of Baluchitherium, can be seen in the palæontological gallery of the British Museum (Natural History).

Nutrition Problems during Famine Conditions in Russia.

By Prof. BORIS SLOVTZOV, Professor of Biochemistry at the Medical Institute for Women at Petrograd.

I AM glad that it has fallen to my lot to be one of the first physiologists to get through the cordon which has almost come to be considered as a kind of a second Chinese Wall. Russian scientific men have been cut off from Europe for about eight years, and have therefore been obliged to follow their scientific work in their own way.

Now that we are gradually becoming aware, through the literature and by means of personal observation, of the intensive work that has been done in the West,

especially in England and America, we realise to our dismay how much we are behind in our results, and how bad are the conditions under which we are working and are likely to work for some time. We have, however, in accordance with our possibilities, achieved a certain amount of work which, I hope, may be of interest to our colleagues in physiology and physiological chemistry. I can only give the main results we have obtained, but it provides an insight into the trend of scientific thought which has prevailed in Russia during the period of isolation.

Soon after the post-War conditions had brought about a state of affairs in which it became difficult to feed the population and the available food became less and less, Russian scientific men were faced with the task of investigating various nutrition problems. A number of emergency substitutes such as bran, oil-cakes, straw, etc., were suggested to the public. It became necessary, therefore, to establish a standard according to which the nutritive value of the different substitutes could be assessed. As in Germany, it became at first necessary to prepare bread with various grasses and to mix large quantities of potatoes in the flour. The conditions under which a bread could be prepared that could be employed as a basal-food product had to be worked out. It became necessary to make use of the experience of other countries, especially Austria. At one time the advisability of feeding on whole-meal bread, as was done in Italy, was considered. This, however, was found unsuitable and uneconomical. Then we had to set to work in order to find out how a number of natural foods such as plants and roots, *Lichen islandicus*, *Laminaria digitata*, could be utilised. With this purpose in view, a series of metabolism experiments were carried out with bread to which these substitutes were added. The most successful results were obtained with Laminaria, of which 70 per cent. was utilised by the system; 25 per cent. of Iceland moss and quantities up to 50 per cent. of various green plants were also found to be assimilated. Of course plants are not utilised well, owing to the high content of cellulose, and several methods were considered in order to overcome this difficulty. One way considered was to pulverise the cellulose and free it from lignin; another, to bring the cellulose into a soluble state.

In this connexion a Swedish preparation known as "Swedish flour" was of interest to us. This product consists of pure cellulose and is ideal in its physical consistency. It is light, porous, and does not irritate the intestine in the slightest degree. Metabolism experiments have, however, revealed that the output was equal to the intake, and that there was no utilisation of the product. Occasionally the output was less than the intake, and in these cases the deficit could be accounted for quantitatively as methane in the expired air.

The attempt to utilise bran in its entirety was of greater interest. The bran was mixed and fermented with lactic organisms at 40-45° C. for 15 hours. The cell-membranes were thus disorganised and the cell contents were made available. This can also be attained by means of autolysis by increasing the acidity with lactic acid to a strength of 0·1-0·15 per cent. When autolysis is complete, flour can be added and the mixture made into dough and baked. Bread prepared in this way was found to be utilised 5-6 per cent. better than a control bread, especially as regards protein. It contained a large amount of protein matter and vitamins. The liquid obtained by autolysing in acid medium or by fermentation with lactic organisms can also be utilised mixed with agar and gelatin as a nutrient medium for organisms.

A special commission was engaged in investigating the nutritive yeasts. The physiological and medical part of this investigation was worked out under my own supervision. It was established that *nutritive* yeast, beer yeast, and dried yeast form ideal foods rich in protein. Up to 85-90 per cent. of the material is assimilated, and palatable dishes can be prepared from it. Yeast alone cannot sustain life, as it does not contain fats and vitamin-A. If, however, yeast is mixed with a good fat it is capable of maintaining the existence of rats and mice.

Yeast, like meat extracts, promotes the secretion of the gastric and pancreatic juices, and greatly stimulates the action of salivary amylase and of trypsin. An adult organism can tolerate as much as 100 gm. of yeast without harm. Only a slight increase in the output of uric acid was observed. I am not going to discuss now the pharmacological side of this food, but I may say here that it stimulates growth in children and in animals, and that it increases the formation of hæmoglobin in blood in general.

Our interest in yeasts for nutritive purposes made us also investigate the part played by "mineral" yeasts which the Germans cultivated on ammonium sulphate and glucose. These are usually a mixture of bread yeast and *Mycoderma cerevisiæ*. They were found to be of little use for nutrition purposes.

Much more interesting were the results we obtained with the so-called "Fetthefe." The Germans wanted to utilise this substance as a source of fat, but were not successful. We adopted a different procedure from theirs. Cultures of *Endomyces vernalis* under certain conditions can produce as much as 18 per cent. fat calculated on dry matter. The investigation of the fat has shown that it mostly consists of triglycerides and resembles olive oil in composition. It is well assimilated. To prepare the fat by cultivating the organism in bottles was of course too expensive, and we adopted the following method of cultivation. Potatoes and other vegetables poor in fats and protein were sterilised and inoculated with *Endomyces vernalis*. After 5-6 days' growth the medium was dried. The product thus obtained is rich not only in carbohydrates but also in nitrogenous substance and in fat, and can, like the flour, be employed as a new article of food. As such it can be assimilated by human beings. Experiments are now in progress for the purpose of applying this process to animal nutrition.

When the famine abated the dietetic investigations became less urgent. Russian physicians and physiologists, however, collected interesting material concerning starvation. It is difficult to imagine the degree of starvation. The table below gives the official standard ration of the population according to status and age for most categories of Russian populace. Human life could not continue under such conditions, and the mortality was great.

OFFICIAL RATION, JANUARY 1, 1920.[1]

	Number of Persons.	Mean Calories per Person.
Hospitals	36,044	1805
Children's Hospitals	..	1513
Houses of Detention ?	6,214	1414
Asylums and Settlements	29,887 + 754	1828
Workers' dinner	..	424
Ordinary dinner	612,030	265
Children's dinner	..	408
Typhus ration	8,670	1937
Invalids' ration	1,200	1645
Ration of Red Army behind the lines	13,710	1507
Scientific specialists	..	2761
Learned men's ration	1,800	3600
Iron and wood workers	..	4600

In Petrograd and Moscow the famines were investigated in fairly great detail, and scientific material was obtained for two great conferences on the famine, the deliberations of which have so far not been published. As a president of one of these conferences I can give the most important and interesting points which have been elucidated and which are of interest from the physiological point of view.

First, the approximate weight of the body was ascertained, according to the French formula that when the length of the body in centimetres is multiplied by 0·4 the weight of the body in kilograms is obtained. We have measured the height and weight of many persons who died of starvation without any other complications, and the weight according to the formula was found to be 30-35 per cent. less than the normal. Thus the figures obtained on starving animals have been confirmed on human beings.

Chemical analysis of the organs of people who died from starvation has shown a great deviation from the normal, especially in the content of neutral and phosphorus-containing fats. There was a small decrease in weight in all organs with the exception of the brain. This had already been ascertained through laboratory experiments. Chemical analysis of the white and grey matter has further revealed a great change in the tissue of the grey matter by a large diminution, not only in the phosphorus-containing fats, but also in the general quantity of the protein. In certain cases this diminution was as much as 25 per cent. The small fall in weight in the brain can, therefore, be explained by the fact that the white matter which forms the greater part of the brain is least altered, while the grey matter is changed greatly in quantity and especially in quality.

Secondly, an experiment was carried out on a large scale to ascertain the influence of the absence of fats from the diet; a mass experiment which lasted about two years. Trading in food products was forbidden and the transport was disorganised. Consequently, a rationing system was enforced on the population. At first the rationing was restricted to bread only. After the second revolution, however, the population was divided for rationing purposes into four categories. The first consisted of workers, the second of officials, the third of the ordinary citizens, and the fourth of the former rich. The following table gives the actual rations. Afterwards every ministry undertook the rationing of

THE DAILY RATION OF THE FOUR CATEGORIES OF THE PETROGRAD POPULATION.

	Protein.	Calories.
1st Category	74 gm.	475
2nd ,,	40 gm.	240
3rd ,,	33 gm.	135
4th ,,	13 gm.	53

their own officials, leaving the general public on the above diets. I had the opportunity of obtaining the information dealing with the amount of food served out to a certain number of people during the period of two years. From these data it was possible to calculate the fat, protein, and carbohydrates consumed per person per day and to plot mortality curves according to diet.

The first maximum of mortality coincided with the general low intake of calories. During this period many people died. Before death, which occurred generally from intercurrent infections, they mostly manifested œdema. A very high mortality from insignificant causes was also registered during this period. The second mortality maximum coincides with the fat minimum. There were days when the daily fat intake averaged about 5 gm.—to all intents and purposes a fat-free diet. During this period deaths of undefined character were registered. The organs of the victims showed scarcely any change.

In the course of the famines it was also possible on several occasions to confirm the influence of the vitamins on human beings. It is interesting to record an outbreak of scurvy among various groups of people whose diet was quantitatively quite satisfactory, but lacked variety and consisted mainly of ingredients such as boiled millet, maize, etc. Such an outbreak took place in the fleet. The pathological change in the large intestine which was brought about by the one-sided consumption of millet was even named "Millet disease." The mucous membrane is penetrated by the small grains, which cause intense inflammation. By changing the diet and using large grains only this scurvy-like condition is cured. This confirms the work of American workers, showing that the physical condition of the food may be responsible for a change in the mucous membrane of the intestine, which may favour infection. Scurvy is a dietetic disease due to a deficiency of vitamin-C. and a consequent bacterial infection. No specific organism causing scurvy could be found.

Further, investigations during the famine have shown that the relative proportion of protein, fat, and carbohydrate in the diet play an important part in the nutrition of the infant. A great deal of information was obtained from infant institutions where, owing to the lack of fats, grave illnesses were prevalent, which, however, disappeared when butter was introduced in the diet. It is of interest to record the great diminution in the fertility of women and the cessation of the menstrual periods. Similar conditions were observed among animals by the veterinary surgeons.

[1] Although these amounts represent what it was proposed by the Government to provide, no doubt the actual supply often fell short of the quantities set forth in the table.—Editor of NATURE.
